## Validation: facts and controversies

The desire to validate simulators has been an important and necessary effort from the very beginning. After all, we need to know if time spent on a simulator provides value. Today we have a tendency to use the term *validation* in a generic sense of "does it do what it is supposed to do?" We need to consider this term from different points of view. While the surgical community considers simulators to prepare for patient care and increase safety, the education community talks about formative feedback and summative evaluation. Many important questions have been combined under this rubric, each with their own challenges:

- If I keep practicing on a simulator, do I get better?
- If I keep practicing on a simulator, do I get better in the operative room?
- How many times should I repeat an exercise or how long should I practice until I am done?

Let's consider these questions individually. If you keep practicing on a simulator you will always get better at doing that *specific* task on a simulator, which does not necessarily relate to the surgical task that we are preparing for. The second question moves us closer in that direction as it considers training transfer. Indeed, if the simulator was not designed properly you might actually get better on the simulator but worse in the operative room, which is known as negative training transfer. The third question, although not directly related to validation, is also a critical one. Unfortunately it is neither time nor repetition that can establish an end point. The correct answer has to be "until you reach proficiency," as each individual learns at a different rate. The only thing that really matters is that, whenever a trainee stops practicing on the simulator they must be deemed safe to take care of patients.

To further complicate the notion of *validating* a simulator, we need to consider some other items:

- Did the trainee properly study the didactic content preparing them for the exercise?
- Has a mentor observed and provided the trainee with formative feedback so that they get better at what they are doing?
- Was the trainee instructed properly on how to practice on the simulator?

If trainees do not understand the instructions, the simulator might not help them and, at the same time, even a mediocre simulator could allow them to learn if they were working with an excellent mentor.

None of these questions directly relate to validation as defined by the educational community, which will clearly state that one can only validate an assessment instrument, to basically state that it correctly measures what was intended to be measured. That process is rigorous and complex, reflected in the fact that there are very few simulators that are *formally* validated. The standards for validation are published in *Standards for Educational and Psychological Testing*, 2014 edition [60].

Validation is not a process that can be undertaken as an afterthought, as it relates to intent: what were the learning objectives we had in mind? How are we assessing that these learning objectives are reached? What is the prescribed training protocol? As the Holy Grail is to assess whether time spent on a simulator translates to better patient care, we also should create assessment instruments that can be used both with the simulators and in the clinical environment. Then we could compare data directly and determine whether or not training transfer took place.

## The role of assessment and certification

When discussing training, we also need to consider assessment. Without assessment we cannot tell if training is leading to improvement. Without assessment we cannot tell the trainees how to improve their performance, or decide if the trainee is ready to move on to the next level.

Creating a reliable assessment instrument is a difficult task. For example, time to completion has been widely used for assessment of technical skills, while studies have shown that time is *not* a valid measure for surgical performance; in fact, speed increases errors. In 1990 Miller created a template for the assessment of cognition and behavior in a clinical setting (Figure 75.9) [61]. He underlined the importance of separating the assessment of cognition from behavior: the examinee shows the they *know* the basic science and demonstrates that they *know how* to relate it to the procedure. After demonstrating cognitive skills, the trainee *demonstrates how* they apply their cognitive knowledge to the procedure and, finally, that they are able to actually *do* it. This whole process reminds us once again of the procedural training template depicted in Figure 75.2 and of the relevance of modular hands-on training as a pattern of step-by-step skills assessment, during the "show how" phase. Assessment may include evaluation of both technical and nontechnical skill markers, such as the Global Evaluation and Assessment of Robotic Skills (GEARS) [62] and the Non-Technical Skills for Surgeons (NOTSS) [63]. Crowdsourcing is now also being studied as an alternative to conventional tools, mostly based on expert evaluation. Indeed recent studies [64, 65] demonstrate how "crowd scores can provide similar or nearly identical concordance with faculty panel ratings and pass-fail decisions" in approximately 48 hours, which is 60 times faster than the expert counterpart. Moving ahead, electronic sensors or video analysis could improve the measurement of technical skills, just as VR-based simulators claim to do.

Indeed, relying on a solid assessment tool is critical when we talk about certification and licensing. In 2009, the American Board of Surgery (ABS) mandated that, in order to be eligible to sit for the board exam in General Surgery [66], a certificate documenting the successful completion of the FLS exam had to be

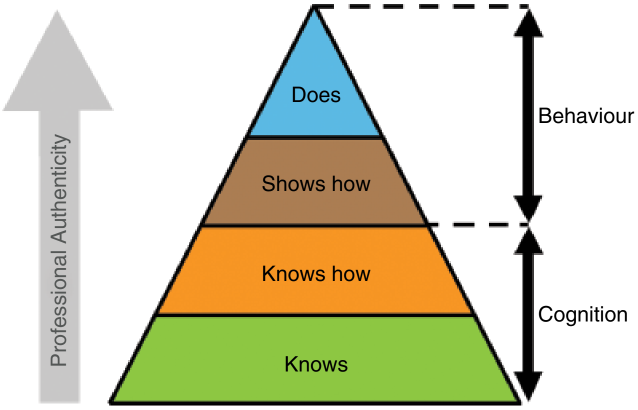

**Figure 75.9** The assessment of clinical skills/competence/performance.

submitted along with the application. Similarly, the E-BLUS exam includes an online cognitive part to be completed before moving on to the technical skills part, to be certified. Creating a high-stakes exam requires tremendous scrutiny and rigor. When a surgical society endorses an exam as "high stakes" it certifies that, by passing the exam, the applicant is considered by the society competent to perform the procedure with full autonomy. Urology board certifications in America, Europe, and Australia include today only cognitive assessment and rely on logbooks to certify practical skills. The addition of technical skills assessment as an integral part of board exams would definitely improve the validity of these high-stakes exams, leading to improved patient safety.

As documented in the literature, assessment and certification in surgery are evolving with much room for improvement. Considering the role of simulators in civil aviation training, licensing, and re-certification today, it would not be a surprise to see similar requirements in the laparoscopic and robotic surgery fields in the years to come.

# Patient Preparation and Operating Room Setup for Laparoscopic and Robotic Surgery

*Weil R. Lai*[1] *& Benjamin R. Lee*[2]

[1] *Department of Urology, Tulane University School of Medicine, New Orleans, LA, USA*
[2] *Division of Urology, University of Arizona College of Medicine, Tucson, AZ, USA*

## Introduction

Laparoscopic and robot-assisted procedures have become the cornerstone of a urologist's surgical armamentarium over the past two decades. These minimally invasive procedures require additional equipment and operating room setup. Patient and operating room preparation are key features to successful and efficient surgery.

It is imperative that the operating room personnel and surgeon are familiar with all equipment systems and proper preparation of equipment. Urology surgical team members also need to be able to troubleshoot unexpected occurrences during a case. Without proper preparation and positioning, patient safety and surgical outcomes may be compromised. In this chapter we describe key features of patient preparation and operating room configuration for common laparoscopic and robotic surgeries.

## Patient preparation

Careful patient selection for minimally invasive urologic procedures is critical for successful outcomes. Patient selection begins with a thorough history and physical examination, including attention to cardiopulmonary status and previous abdominal surgeries. Medical and/or cardiovascular clearance may be warranted. Patients with chronic obstructive pulmonary disease require pulmonary clearance, including pulmonary function tests, because of the risk of hypercarbia. Appropriate laboratory data, such as complete blood count, basic metabolic panel, prothrombin time, partial thromboplastin times, and urinalysis with culture should be considered. Radiologic imaging is helpful for surgical planning. For example, computed tomography (CT) with intravenous contrast is valuable for delineating the renal vascular supply for laparoscopic nephrectomy or partial nephrectomy, or for identifying crossing vessels prior to pyeloplasty.

The indications for laparoscopic and robotic urologic procedures are almost identical to those of open surgery. Absolute contraindications to minimally invasive surgery include uncorrectable coagulopathy, abdominal wall infection, massive hemoperitoneum, and generalized peritonitis [1]. Intestinal obstruction was formerly considered an absolute contraindication; however, many general surgeons will perform diagnostic laparoscopy for small bowel obstruction if the bowel is not too dilated. Historically, relative contraindications to minimally invasive surgery included morbid obesity, extensive prior abdominal/pelvic surgery, pelvic fibrosis, organomegaly, ascites, pregnancy, hernias, and iliac or aortic aneurysms. However, in this current day and age laparoscopic and robotic surgery can be safely performed in patients with morbid obesity and previous abdominal surgery with minor technical adaptations. For example, Trocar placement for laparoscopic renal surgery can be shifted laterally for obese patients and the Veress needle can be introduced off site from abdominal scars in patients with previous abdominal incisions during initial insufflation. Pregnancy is no longer considered a contraindication for laparoscopy.

## Informed consent

All patients should understand the risks, benefits, and alternatives of the proposed procedure. Complications associated with minimally invasive procedures are

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

Companion website: www.wiley.com/go/smith/textbookofendourology

similar to their open counterparts with the exception of a few unique complications, including $CO_2$ embolism, hypercarbia, postoperative crepitus, and shoulder pain from pneumoperitoneum. Every patient who undergoes a laparoscopic or robotic procedure should understand the potential for conversion to an open procedure and this should be documented in the written consent.

### Consent for blood products

For surgeons who have experience with laparoscopy, blood type and screen can be sufficient for most minimally invasive urologic procedures. Type and cross for 2 units of packed red blood cells is appropriate for more extensive procedures, such as partial nephrectomy and radical cystectomy. We do not recommend preoperative donation of autologous blood prior to robot-assisted radical prostatectomy because of lower estimated blood loss due to pneumoperitoneal compression of venous blood supply with the laparoscopic approach [2].

## Bowel preparation

Preference for bowel preparation varies from surgeon to surgeon. It is our recommendation that patients take a half bottle of magnesium citrate the day before surgery for transperitoneal laparoscopic or robotic renal procedures. Many minimally invasive urologic surgeons do not routinely administer a bowel preparation prior to laparoscopic or robotic renal or prostate surgery.

Our preference for bowel preparation prior to robot-assisted radical cystectomy is mechanical bowel preparation only with an oral electrolyte solution. We no longer routinely administer antibiotic bowel preparation (i.e. oral neomycin and metronidazole); however, broad-spectrum antibiotics are administered intravenously within 60 minutes of incision.

## Operating room setup

Operating room setup, experienced nursing staff, and a team approach are keys to a smooth procedure. All operating room personnel should be familiar with the operating room setup and basic equipment function. Minimally invasive procedures require more equipment than standard open procedures; thus, the operating room should be large enough to accommodate the laparoscopic tower and the robotic system.

All equipment should be tested prior to each procedure to make sure it is functional, including the aspiration–irrigation system, electrocautery, $CO_2$ insufflation, camera, and light source. If anticipated to be used, the argon beam electrocautery or saline-enhanced radiofrequency cautery should also be tested prior to partial nephrectomy. Lists of equipment necessary for laparoscopic and robotic renal surgery, as well as robotic pelvic surgery, are given in Boxes 76.1–76.3. An open tray should be either set up or immediately available in the room in the event rapid conversion to open surgery is needed.

The room configuration for renal surgery varies from left to right side and from laparoscopic to robotic cases. Aerial diagrams of room setup for laparoscopic transperitoneal renal surgery and robotic pelvic surgery are shown in Figures 76.1–76.3.

Most laparoscopic renal surgeries are performed with the surgeon and assistant on the same side of the table. Thus, two video monitors are ideal with the main laparoscopic tower (containing video monitor, light source, camera, and insufflators) placed on the side opposite the surgeons. The $CO_2$ insufflator is placed in the surgeon's view to allow for continuous monitoring of the intraperitoneal pressure. The second video tower is placed in view of the second assistant and the scrub nurse who are stationed on the side opposite the surgeons along with the instrument table. Incoming lines from the camera, light cord, $CO_2$ insufflation tubing, aspiration–irrigation tubing, and electrosurgical devices enter from the contralateral side of the table or from the head or foot of the table. Additional lines from equipment, such as a Harmonic scalpel, LigaSure (Covidien, Boulder, CO, USA), or argon beam coagulator, should be arranged in an orderly fashion to prevent them from getting tangled during surgery. Pre-existing or improvised pockets in the laparoscopic drape can be helpful for organizing equipment.

**Box 76.1 Basic equipment for laparoscopic surgical procedures.**

Mobile video cart with monitor
Secondary video cart
$CO_2$ insufflator with $CO_2$ tank or wall supply
$CO_2$ insufflation tubing
Camera, high resolution, and control box
0 and 30° 5- or 10 mm laparoscopes
Scope warmer
High-intensity light source
Fiberoptic light cable
Electrosurgical cords
Electrosurgical unit with foot pedal (monopolar, LigaSure, HARMONIC, ENSEAL, and/or Thunderbeat)
Aspiration–irrigation system with double canister suction apparatus
High-definition video recorder (optional)

### Box 76.2 Equipment for laparoscopic renal surgery.

One Veress needle
One 5 mm Trocar
Two 12 mm Trocars
One aspiration–irrigation tubing and probe
Two 5 mm laparoscopic atraumatic grasping forceps (blunt)
One 45 mm endovascular stapler
Two endovascular stapler reloads
One 5 mm laparoscopic monopolar scissors

*Additional equipment for laparoscopic partial nephrectomy*
Four bulldog clamps with remover
Two 5 mm laparoscopic needle drivers
One Satinsky clamp
Additional 12 or 15 mm Trocar for assistant
Laparoscopic ultrasound
0 polyglactin CT-1 suture
FloSeal Hemostatic Matrix (Baxter, Deerfield, IL, USA)
Mini-laparotomy pads
Hem-o-lok ligation system (Teleflex Medical, Research Triangle Park, NC, USA)
Lapra-Ty absorbable suture clips (Ethicon, Somerville, NJ, USA)
2-0 polyglactin SH suture
Closed suction drain

*Additional equipment for robot-assisted procedures*
0 and 30° robot camera lens
One robot fenestrated bipolar grasper
Two robot large needle drivers (Mega cut, Large needle driver)
8 mm robot Trocars
One robot Prograsp grasper
One robot monopolar scissors

During robotic procedures the surgeon console can be positioned in a corner of the operating room, depending on room configuration. In the newer-generation robotic surgical systems, the optical viewer, arm rest, and foot pedals can be easily adjusted for surgeon comfort. For robotic renal surgery, the assistant is positioned on the

### Box 76.3 Equipment for robot-assisted laparoscopic radical prostatectomy.

One Veress needle
Four 8 mm robotic Trocars (for da Vinci S, Si, Xi, X)
One 12 mm Trocar
One 5 mm Trocar
One aspiration–irrigation tubing and probe
Robotic monopolar scissors
Robotic fenestrated bipolar grasper
Robotic Prograsp grasper
One 5 mm laparoscopic needle driver
One 5 mm atraumatic grasping forceps
Hem-o-lok ligation system (Teleflex Medical, Research Triangle Park, NC, USA)
One 2-0 polyglactin CT-1 suture cut to 10 inches for dorsal vein stitch
One 3-0 barbed poliglecaprone RB-1 suture for posterior reconstruction stitch (optional)
Two 3-0 barbed poliglecaprone RB-1 suture as a "double-armed" stitch
One 10 mm Endocatch bag
One 18 Fr Foley catheter (intraoperative catheter)
One 20 Fr Foley catheter (final catheter)
Closed suction drain

side opposite the surgical site. For robotic pelvic surgery, the authors' preference is for the bedside assistant to sit or stand on the patient's right side with the scrub nurse on the patient's left side. One advantage of having the scrub nurse and assistant on opposite sides of the table is that the scrub nurse can be positioned close enough to the table to actively participate in the surgery, such as during Foley catheter manipulation and for applying perineal pressure. A disposable plastic instrument holder can be secured to the laparoscopic-assisted vaginal hysterectomy (LAVH) drape next to the bedside assistant for convenient intraoperative storage of frequently used instruments. This helps minimize instrument passage across the patient's body. Alternatively, a sterile Mayo stand can be positioned next to the bedside assistant as a "mini table" to hold the frequently used instruments. It should be noted that some surgeons prefer the bedside assistant to be located on the patient's left side, allowing the fourth arm to be placed on the patient's right side and the two grasping instruments to be used simultaneously. A second video monitor is helpful for the remainder of the operating room staff. If laparoscopic ultrasound is used, the screen should be placed within the assistant's direct line of vision.

Once the robotic and assistant ports are placed, the robot is docked. It is important to align the base of the slave unit with the camera port. This allows for proper docking of the robotic instruments in order to have adequate range of motion and to avoid arm collisions. With the da Vinci Si Surgical System, it is important that the blue arrow on the camera arm be aligned within the "sweet spot" to ensure the slave unit is docked within the correct distance from the operating table to accommodate appropriate range of motion of all instruments. To reduce instrument and robotic arm collisions, the robotic ports are placed at least four fingerbreaths apart from each other, and the elbows of the robotic arms are rotated outwards.

With the da Vinci Xi Surgical System, the patient cart is brought over the patient by aligning the laser crosshairs on the boom over the camera port. With the robot arm docked to the camera port and the camera focused on the target anatomy, the autotargeting button on the camera is pressed to rotate the boom to optimize the position of the remaining robot arms. The robot ports are placed at least 6–8 cm apart from each other. To minimize external robot arm collision, we adjust the space between the elbows of each robot arm to accommodate the size of a hand's fist.

## Patient positioning

### Laparoscopic renal surgery

In traditional open renal surgery, the patient is positioned in flank position in the lateral decubitus position with the kidney rest elevated and the table flexed. In contrast, laparoscopic transperitoneal renal surgery can be effectively performed with the patient in the modified flank position [3] (Figure 76.4). The patient is placed in the supine position with a 4 kg sandbag or gel roll under the ipsilateral side, creating a 30–45° rotation. The bottom leg is slightly flexed at the hip and knee, and the top leg is left straight. Pillows are placed between the legs as a cushion and to slightly elevate the upper leg in line with the torso. The chest and hips are secured to the table with 8 cm silk tape. The ipsilateral arm is then padded and secured in a modified "sling" position, similar to the position used by orthopedics for clavicular fractures. The contralateral arm should be secured to an arm board. All pressure points are padded with egg-crate foam or gel pads. Neither the kidney rest nor an axillary roll is necessary in this modified flank position. The table is then maximally rotated laterally, thus creating a true 90° angle relative to the horizontal. The lateral rotation of the bed should be tested prior to draping the patient and the anesthesia team should ensure patency of arterial and venous access. This positioning is ergonomic for the patient and surgeon.

Positioning for retroperitoneal laparoscopic renal surgery is similar to that for open nephrectomy. The patient is placed in the full lateral position in the center of the table with the table flexed. An axillary roll is placed to prevent brachial plexus injury.

Bilateral lower extremity antiembolic stockings and pneumatic compression devices should be in place prior to induction of anesthesia. An upper body and/or lower intraoperative warming device should be placed before the patient is prepped and draped. There is debate about optimal surgical site preparation and preoperative antibiotics for prevention of incisional infections. A prospective randomized clinical trial comparing chlorhexidine–alcohol to povidone–iodine for surgical site preparation demonstrated a statistically significant reduction in both superficial and deep surgical incisional infections with the use of chlorhexidine–alcohol [4]. The entire abdominal wall should be prepped from the nipples to the pubis. The genitalia should be prepped in the

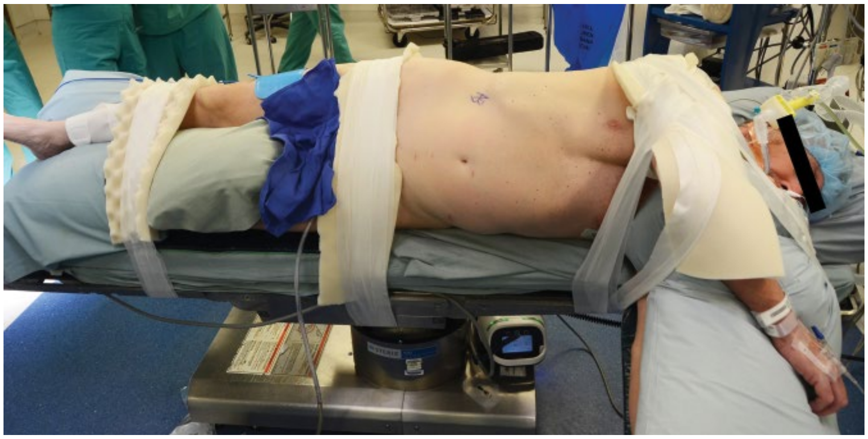

**Figure 76.4** Patient positioned in modified flank position for laparoscopic and robotic transperitoneal renal surgery.

field for minimally invasive nephroureterectomy and ureteral reimplant to allow for sterile Foley catheter placement on the field. Antibiotic prophylaxis should be administered within 60 minutes of the surgical incision. The American Urological Association's best practice policy statement on urologic surgery antibiotic prophylaxis is an excellent resource for selecting specific preoperative antibiotics [5]. Prior to insufflation, an orogastric tube and Foley catheter should be in place in order to decompress the stomach and bladder to avoid inadvertent injury to these hollow viscera.

## Robotic pelvic surgery

For robotic pelvic surgery the patient is ultimately placed in a steep Trendelenburg position with the legs in a low lithotomy position (Figure 76.5). For the da Vinci Xi, we use the split-leg position (without hyperextension of the hip) as the robot docks from the patient's side rather than between the legs (Figure 76.6). This position allows gravity to pull the abdominal viscera away from the operative field and the assistant to access the perineum and genitalia intraoperatively. The operating table is prepared with egg-crate foam taped to the table and a folded sheet placed under the egg-crate foam to facilitate securing the arms. The friction between the egg-crate foam and the patient's skin will help prevent cephalad slippage or movement when the table is in the full Trendelenburg position. Some centers advocate the use of a gel pad instead of egg-crate foam between the operating table and the patient's skin because of reports of chafing and skin breakdown. The patient is placed in the supine position with the buttocks at the end of the table break. Prior to induction of anesthesia, compression stockings and sequential compression devices are placed on the patient's lower extremities. The legs are placed in Allen Yellofin stirrups (Allen Medical Systems, Acton, MA, USA) with the knees flexed. The foot of the table is then lowered until it is perpendicular to the floor. Care should be taken to align the toe, knee, and opposing shoulder, to ensure the heels are touching the heel of the boot, and to check that the calves have adequate space to avoid popliteal artery occlusion, peroneal nerve injury [6], or the devastating complication of lower extremity compartment syndrome [7]. The anesthesiologist should evaluate

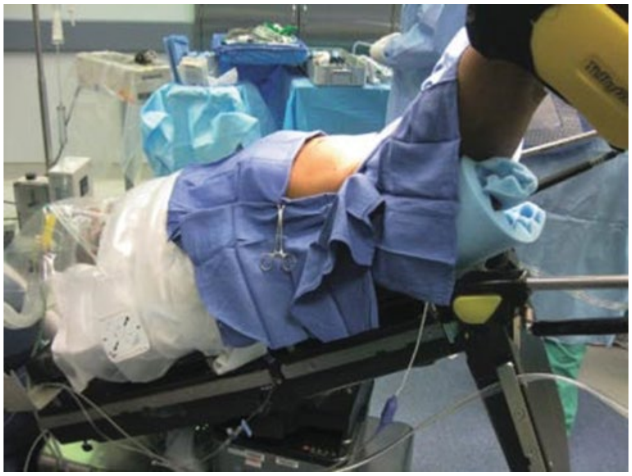

**Figure 76.5** Patient positioning in low lithotomy with the full Trendelenburg position for robotic pelvic surgery.

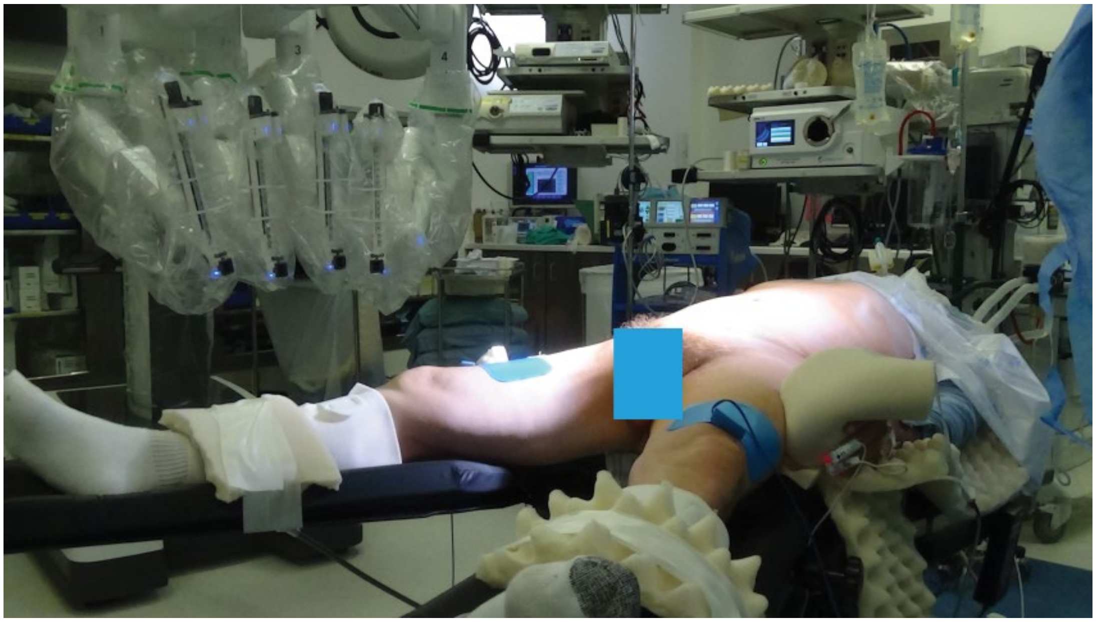

**Figure 76.6** Patient positioning in split-leg position for robotic pelvic surgery.

the position of the patient's head before and after applying the Trendelenburg position in order to monitor for slippage. The arms are tucked at the patient's side with the preplaced sheet under the gel pad. Alternatively, arm sleds can be utilized to secure the arms without tension; however, excess arm compression can result in temporary neuropraxia. The fingertips are positioned at the anterolateral thigh. The elbows and wrists are protected with gel padding, and small foam rolls are placed in the patient's hands. Care should be taken to ensure that vascular lines and the pulse oximeter are properly functioning. The arms should be secured low enough for the prepped field to include the area lateral to the anterior superior iliac crest. Obese patients may require an arm board on the side of the table to support the arms. We do not recommend routine use of shoulder straps or taping the shoulders in a harness fashion because of the risk of brachial plexus injury [8, 9]. We recommend using foam-wrapped 8 cm cloth tape across the chest to prevent cephalad slippage in obese patients only. Care should be taken to ensure the chest tape does not impede mechanical ventilation.

The patient is then prepped and draped from the costal margin to the mid thighs, including the genitalia and perineum. Surgical site preparation and preoperative antibiotic prophylaxis recommendations are the same as for laparoscopic renal surgery. An LAVH drape is useful for robotic pelvic surgery as it is a combination leg and laparoscopic drape. The field is established such that the bedside assistant can have access to the perineum and genitalia for intraoperative application of perineal pressure during initial anastomotic suture placement and for Foley manipulation. An 18 Fr Foley catheter is placed, sterile, on the field and the anesthesia team should place an orogastric tube.

After initial insufflation and port placement, the patient should be placed in a steep Trendelenburg position. For the da Vinci Si and earlier-generation robots, the robot is brought in for docking between the legs. The Allen Yellowfin stirrups should be low enough to accommodate the robot. For the da Vinci Xi robot, our preference is to use the split-leg position and dock the patient cart to the patient's side. Once the robot is docked, there should be no additional manipulation of the table position.

## Positioning pitfalls

Suboptimal positioning can not only lengthen operative times and lead to surgeon frustration, but can lead to devastating complications. Despite proper patient positioning and preparation, patient injuries have been reported as a consequence of positioning during laparoscopic and robotic surgeries [6, 10]. Wolf et al. reported on 1651 procedures that resulted in 46 neuromuscular injuries in 45 patients (2.7%), including abdominal wall neuralgia, extremity sensory deficit, extremity motor deficit, clinical rhabdomyolysis, shoulder contusion, and back spasm. Patients with rhabdomyolysis were more often male, were heavier, and underwent longer procedures. Patients with motor deficits were older. Preexisting nerve dysfunction predisposes patients to motor nerve injury.

It is important for the surgeon to remain comfortable throughout the procedure to avoid pain or fatigue. Interestingly, 28% of surgeons in the 18 academic institutions included in Wolf et al.'s study reported frequent neck pain and 17% reported frequent shoulder pain [6]. Measures taken by surgeons to alleviate neuromuscular strain included lowering the table maximally, using lifts on the floor, altering the manner in which they held instruments (without fingers through the handles), and altering the position of the monitors.

A devastating complication of robotic pelvic surgery is lower extremity compartment syndrome, which can occur when the patient is placed in Allen Yellofin stirrups in the extreme Trendelenburg position. This complication may require lower extremity fasciotomy [7, 11]. Proper positioning is key to prevention, specifically ensuring the patient's ankle, knee, and contralateral shoulder are aligned in the stirrup, and that gel pads are used directly in contact with the patient's skin to avoid cephalad slippage while in the Trendelenburg position. A high index of clinical suspicion will facilitate early recognition and prompt treatment.

There have been reports of patients developing ischemic optic neuropathy after laparoscopic radical prostatectomy, thought to be a result of a combination of long operative time and the Trendelenburg position [12]. Intraocular pressure measurements in surgical patients confirmed a higher intraocular pressure in patients in the Trendelenburg compared to the supine position [13]. However, the direct clinical consequences of sustained elevated intraoperative intraocular pressures are not known.

## Positioning for other robotic procedures

### Other robot-assisted laparoscopic pelvic surgery

Positioning for a robot-assisted laparoscopic radical cystectomy and for robot-assisted ureterovesical reimplant is similar to that for robot-assisted laparoscopic radical prostatectomy. The only difference is shifting port placement slightly cephalad to allow for proximal ureteral dissection and for extended bilateral pelvic lymphadenectomy. The camera port is placed 2 cm above the umbilicus and the two robotic ports are placed approximately at the level of the inferior border of the umbilicus.

### Transperitoneal robot-assisted laparoscopic renal surgery

Positioning for robot-assisted laparoscopic kidney surgery is similar to that for the pure laparoscopic approach. Depending on operating room configuration, the operating table may need to be rotated 90° to accommodate docking the robot. For the da Vinci Si and earlier-generation robots, the robot is docked at an angle from the ipsilateral side of the table in a direct line between the camera port and the renal hilum. For the da Vinci Xi, the robot is docked perpendicular to the patient's back, followed by adjustments with the boom to target its position over the camera port as previously described.

## Conclusions

Time spent properly setting up the operating room and positioning the patient is invaluable. The entire urologic team should be involved in the process with the goal of optimizing outcomes.

## Introduction

Since the advent of robotic surgery less than two decades ago, urologists have been on the leading edge of research into this technology's role in the care of surgical patients. Robotic approaches have now supplanted laparoscopic and even open surgery for many common urological diseases. As the indications and complexity of robotic urological surgery has grown, so too has the body of research describing its relative risks and benefits. Though few randomized trials exist, the common thread among this work is encouraging. Robotic urological surgery is at least as efficacious as the conventional techniques that it complements, often with decreased postoperative pain, less blood loss, faster recovery, shorter hospital stays, and improved cosmesis. Critics of robotic surgery point to higher costs, while other analyses actually suggest potential for substantial cost savings [1]. Additionally, there exists the intangible benefit of improving patient access to minimally invasive surgery not always available with conventional laparoscopy. Much of this work is ongoing, but one thing has become clear: patients who are candidates for robotic surgery pose a unique set of clinical and technical challenges. Knowledge of these factors preoperatively is critical to ensuring the highest likelihood of successful surgical outcomes. The purpose of this chapter is to provide a comprehensive review of patient preparation and operating room setup for robotic urological surgery.

## Patient selection

### History and physical

Many considerations in patient selection for robotic surgery are the same as those for conventional laparoscopic surgery. As with all preoperative consultations, this begins with a thorough history and physical examination. Urologists should pay particular attention to cardiac and pulmonary comorbidities. In all patients, abdominal insufflation with carbon dioxide raises the risk of clinically significant hypercarbia. Patients with chronic obstructive pulmonary disease (COPD) are at particularly high risk. When pneumoperitoneum is combined with steep Trendelenburg positioning for certain pelvic organ access, anesthetic considerations including higher driving pressures for adequate ventilation may arise. Urologists should be similarly cautious in patients with structural cardiac disease. Hypercarbia may be arrhythmogenic in such patients when superimposed on preexisting dysfunction. In patients with these or other concerning comorbidities, preoperative medical consultation for further testing, risk stratification, and medical optimization is reasonable before proceeding with elective surgery. Physical examination in anticipation of robotic surgery is the same as that before any urological surgery. However, one should pay special attention to the presence of surgical scars which may suggest a surgical history that patients have forgotten to disclose. Although some retrospective studies have demonstrated equivalent outcomes in such patients with

Companion website: www.wiley.com/go/smith/textbookofendourology

a history of intra-abdominal surgery who go on to have open or laparoscopic urological surgery, this may be the result of appropriate patient selection rather than true equipoise [2]. Patients with a history of multiple abdominal surgeries may be better served with an open or retroperitoneal approach as indicated.

### Indications and contraindications

The indications for robotic urological surgery are essentially the same as those for the corresponding open or laparoscopic techniques. As the body of comparative research grows, we may soon be able to delineate which patients stand to benefit the most from robotic surgery. In the meantime, the decision is largely a matter of surgeon preference, comfort, technical expertise, and robot availability.

There are relatively few absolute contraindications to robotic surgery. These include uncorrectable coagulopathy, significant abdominal wall infections, massive hemoperitoneum, generalized peritonitis, intestinal obstruction unless accompanied by an intention to treat, and suspected malignant ascites. Given that the majority of urological robotic surgeries are performed on an elective basis, these absolute contraindications to robotic surgery would likely be impediments to the corresponding open or laparoscopic alternatives as well.

In contrast, robotic surgeons disagree more readily regarding the relative contraindications to robotic surgery. The most well studied of these is obesity. Urologists have traditionally hesitated to offer robotic surgery to morbidly obese patients out of a concern for the physical constraints imposed by a thick body wall. This includes the possibility of inadequate robotic instrument length, a decreased ability to pivot Trocars, and higher pressures required for equivalent pneumoperitoneum. Recent work has validated some of these concerns, with a study of over 1600 robot-assisted radical prostatectomies demonstrating increased operative time and estimated blood loss in patients with a body mass index (BMI) over 40 kg/m$^2$ [3]. Garcia-Roca et al. reviewed their experience with renal transplantation in patients with an even higher BMI cutoff of 45 kg/m$^2$; their group found no difference in patient and graft survival rates [4]. Surprisingly, it remains less clear whether the risk of complications with robotic surgery in obese patients is related to the degree of obesity. Two recent studies of patients undergoing robot-assisted radical prostatectomy (RARP) demonstrated conflicting results. Khaira et al. found that BMI >30 kg/m$^2$ was associated with longer anastomotic times, but that there was no significant difference in the total duration of surgery or the frequency of postoperative complications [5]. In contrast, Ahlering et al. found that obese men with BMI >30 kg/m$^2$ had more surgical complications and a slower recovery of urinary function, and required more time to return to baseline activities after RARP [6]. Although obese patients in this study had high levels of preoperative urinary and sexual dysfunction that may have confounded these findings, this serves as an important reminder for urologists to counsel obese patients about their increased surgical risk, even when the surgery is performed robotically.

Other relative contraindications to a robotic approach include pelvic fibrosis, organomegaly, large-volume ascites, hernias, vascular aneurysms, and pregnancy. The last of these is controversial, with some arguing that robotic surgery may still be performed safely in pregnant women. O'Connor et al. reported performing laparoscopic nephrectomy in a pregnant woman, which has now been replicated robotically by Ramirez et al. [7, 8]. When urologists have access to a multidisciplinary team including specialists in obstetrics, anesthesia, and high-risk maternal fetal medicine, gravid women may be reasonably counseled about the risks and benefits of undergoing robotic urological surgery. Further research is necessary to precisely delineate the risks and benefits of robotic urological surgery in this high-risk group.

Irrespective of the presence of relative contraindications to a robotic approach, all patients should be counseled preoperatively about the risk of conversion to an open procedure. Contemporary analyses suggest that this risk is somewhere between 1 and 3% in case series of robotic nephrectomy and prostatectomy, as an example [9, 10]. The conversion rate may be elevated for high-risk patients and those surgeries done at low-volume centers, although retrospective studies are likely affected by patient selection, with high-risk patients encouraged to undergo forego robotic surgery, thus lowering the resulting conversion rate [9].

## Patient preparation

Urological and general surgery have both seen recent paradigm shifts in the management of anticipated postoperative ileus. Whereas extensive bowel preparations preoperatively and prolonged bowel rest postoperatively have long been the norm, both conventions are now being questioned. In one large study of over 700 men undergoing radical prostatectomy with or without preoperative mechanical bowel preparation, Sugihara et al. found no difference between the two groups with respect to overall complications, operative time, length of stay, and total costs [11, 12]. Perhaps even more convincingly, Ramirez et al. performed a systematic review to describe the incidence of postoperative ileus in patients after radical cystectomy with all types of urinary diversion [13]. Not only did mechanical bowel preparation fail to prevent postoperative ileus, but in many studies was in fact associated with a prolonged time to first bowel movement [13]. Although practice patterns continue to vary, such data have been used to guide the continued refinement of early recovery care pathways for patients undergoing urological surgery [14].

Other components of preoperative preparation are either less standardized or have not yet been studied rigorously. Most urologists elect to type and screen patients preoperatively, rather than to crossmatch for blood. Studies of robot-assisted partial nephrectomy versus open nephrectomy have demonstrated lower transfusion rates for the robotic cohort [15]. Similar data exist for large studies of patients undergoing robot-assisted radical prostatectomy, who require fewer transfusions than do those who undergo open surgery [16]. Additional preoperative preparation is largely driven by individual patient needs. The American Urological Association (AUA) has issued a comprehensive best practice policy statement on perioperative antimicrobial prophylaxis, and should be used to guide decision making for robotic surgery as well [17].

## Operating room

### Robotic surgical system components and physical setup

The physical layout of operating rooms used for robotic urological surgery varies. However, adherence to certain key principles is necessary to ensure optimal patient outcomes and to minimize costly operative time. First, the room size itself may become rate-limiting; operating rooms used for robotic surgery must not only accommodate a large amount of additional equipment, but be large enough to facilitate variable patient positioning and the movement of robotic components. The robotic surgery platform that is currently in widespread use is the da Vinci Robotic System (Intuitive Surgical, Sunnyvale, CA, USA). This system is composed of three main components: the patient-side cart (robotic tower), the surgeon console, and the vision system (Figure 77.1). The patient-side cart is the operative component or “slave” unit of the system which contains robotic arms that hold the Endowrist instruments that are used to perform surgery. The surgeon console consists of the stereo viewer that integrates the imaging of the surgical field acquired by the endoscopy, the master controller by which the surgeon can manipulate the surgical instruments, and foot pedals which control camera movement, robotic arm selection, and energy delivery. Additionally, a central touchscreen control panel allows for management of various functions. The vision system houses the image processing equipment, light source, insufflator, and electrosurgical unit, along with a monitor and various minor components. The specific positioning of these components depends on the constraints of individual operating rooms, as well as patient positioning for the procedure in question. The introduction of the da Vinci Xi system allows for flexibility in operating room setup as the new device enables improved anatomic access regardless of

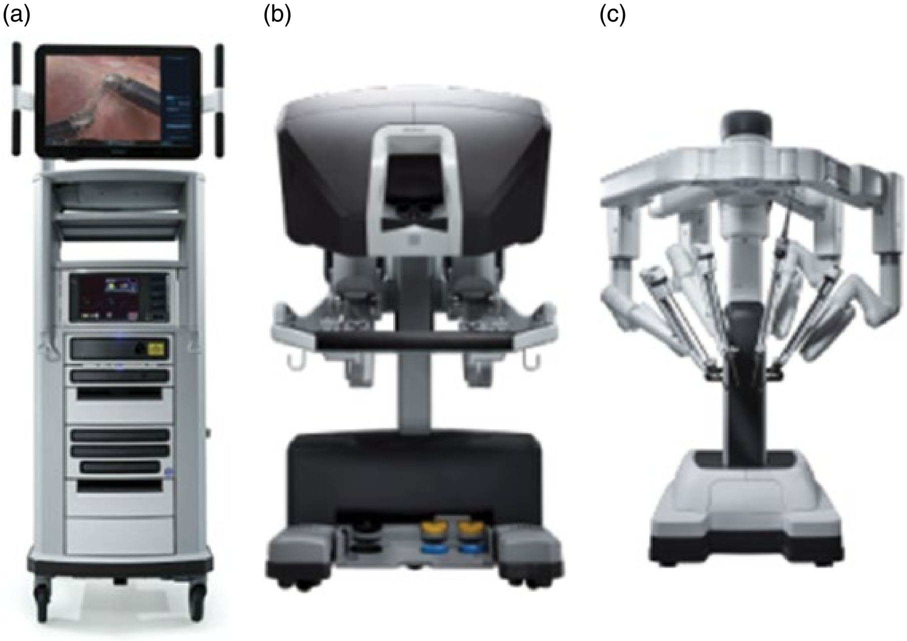

**Figure 77.1** (a) da Vinci Xi vision cart, (b) surgeon console, and (c) patient-side cart. *Source:* Intuitive Surgical, Inc., Calfiornia, USA. Reproduced with permission of Intuitive Surgical, Inc.

patient-side cart position and allows the endoscope to be placed via any surgical port. Longitudinal studies suggest that the presence of ancillary staff who are familiar with and can efficiently troubleshoot the robotic surgery equipment is critical to success [18]. Lastly, but importantly, all operating rooms equipped for robotic surgery should have a complement of open instruments either open or immediately available, should the need for them arise. A complete list of suggested basic equipment for robotic surgery is provided in Box 77.1.

[c] For Xi system an additional robotic Trocar is used as a camera port.

## Patient positioning: general concepts

As with all types of surgery, patient positioning for robotic urological surgery is largely predicated on the anatomical site in question; preparation and positioning for flank surgery is inherently different from pelvic surgery. However, certain principles are universal. Patients should be positioned in ways that maximize access for robotic instruments, are ergonomic for the assistant, and minimize the likelihood of positioning-related complications. Primary considerations in positioning include individual surgeon preference, surgical approach (transperitoneal vs. retroperitoneoscopic), laterality, and organ of interest.

## Patient positioning: retroperitoneal kidney

For retroperitoneal surgery in the upper abdomen, the patient is placed in the lateral decubitus position, with the site of interest easily accessible. The patient’s bottom leg is flexed, the upper leg straight, and all pressure points are padded with pillows, foam, and typically an axillary roll. The table is flexed to increase the distance between the 12th rib and the iliac crest, maximizing access to the flank. Following port placement, the assistant remains facing the front of the patient. The robot patient-side cart is then docked on the contralateral side (i.e. the patient’s back), or from the side of the patient’s head (Figure 77.2).

## Patient positioning: transperitoneal kidney

For transperitoneal surgery in the upper abdomen, a modified lateral decubitus position is used (Figure 77.3). The robot is docked from the table’s contralateral side (Figure 77.4). This maximizes the assistant’s mobility while minimizing interference from the robotic arms.

## Patient positioning: pelvic

Lastly, for pelvic surgery, the patient is placed in the Trendelenburg position, either supine (da Vinci Xi) or with the legs either on split-leg positioners or in stirrups (da Vinci Si) (Figure 77.5). The additional mobility and rotational capability of the Xi patient-side cart allows for positioning at the patient’s side. However with the Si, the patient-side cart is docked between the patient’s legs, allowing the assistant to stand on either side (Figure 77.6). The addition of auxiliary video monitors provides flexibility in the location of the bedside assistant, can limit the necessity of moving the vision tower for different procedures, and provide a view of the procedure for the scrub assistant throughout the case.

## Complications

Failure of the da Vinci system itself is quite rare, and likely becoming even more so as surgeon and engineering experience grows. In a single institution study of 1797 procedures performed with the early da Vinci S system from 2005 to 2008, there were 43 cases of mechanical failure (2.4%). However, these required that only three cases (0.17%) be converted to open or laparoscopic approaches [19]. In a larger study of 11 high-volume institutions performing over 8000 robotic cases, the rate of critical failure causing either conversion or case cancellation was 0.4% [20]. While such events are clearly problematic and reinforce the need for appropriate preoperative patient counseling, they are exceedingly rare and often outside of the surgeon's purview.

In contrast, urologists must remain constantly vigilant of the pitfalls of positioning when preparing patients for robotic surgery. These dangers are similar to those seen with other types of surgery. However, because robotic surgery often prolongs operative time, patients are exposed to these dangers to a greater degree. For example, the use of stirrups is associated with popliteal artery occlusion, peroneal nerve injury, and even lower-extremity compartment syndrome. In one study of 17 high-volume centers performing RARPs in the United Kingdom between 2004 and 2011, lower-extremity compartment syndrome was diagnosed following nine of 3110 procedures, for an incidence of 0.29% [21]. Although this rate is low, seven of nine patients went on to require lower extremity fasciotomy. The authors identified console time over 4 hours, early surgeon learning curve with fewer than 20 robotic cases, BMI >30 kg/m$^2$, and peripheral vascular disease as risk factors [21]. Although some of these risk factors are not easily modifiable, this study serves as an important reminder for the surgeon to check all aspects of positioning before beginning a case.

Reproduced with permission of Intuitive Surgical, Inc.

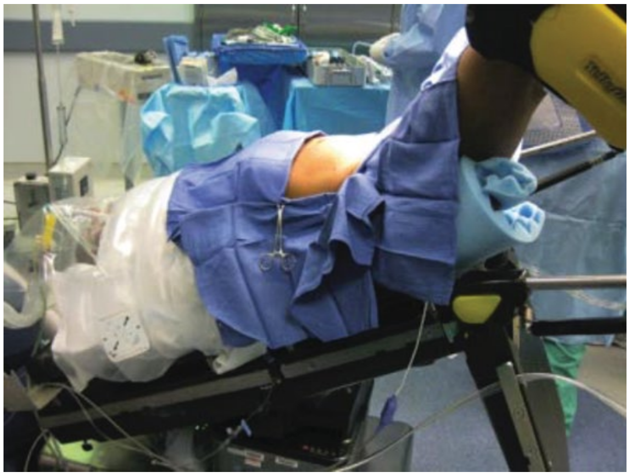

**Figure 77.5** Patient positioning in low lithotomy with legs in stirrups for pelvic surgery.

Similar risks exist to a patient's upper extremities. Older laparoscopic literature suggests that patients may be at risk of abdominal wall neuralgias, injuries to peripheral nerves, and musculoskeletal injury [22]. These same risks would be expected for robotic approaches to urological surgery, given the similarities in positioning. Case reports have now emerged of neurological injury following robotic surgery. In one study, Devarajan et al. identified three patients with upper and middle brachial plexus trunk injury following RARP [23]. The authors theorized that positioning in steep Trendelenburg caused abnormal distraction forces on the abducted arm, which over several hours led to brachial plexus neuropathy [23]. Echoing similar research described above, the authors argued for particular caution in patients who undergo cases with a prolonged operative time.

An additional complication that is thought to be related to positioning in steep Trendelenburg is the development of ischemic optic neuropathy (ION). This phenomenon was described by Weber et al. after two patients developed postoperative ION following laparoscopic radical prostatectomy. The authors theorized that this complication was due to venous stasis and facial edema caused by a prolonged surgical time with the head of the bed down [24]. Alarmingly, similar findings and even complete postoperative visual loss have now been reported after robotic pelvic surgery [25]. To clarify this relationship, Wen et al. used a national database to identify positioning-related complications in patients following robotic or conventional laparoscopic radical prostatectomy [26]. Although ocular complications contributed the most to the overall cohort's complication rate of 0.4%, the authors found that robotic surgery was associated with a decreased risk as compared to conventional laparoscopy [26]. Further research is clearly necessary to delineate risk factors such that urologists may take pre-emptive steps to minimize the likelihood of positioning-related complications.

## Conclusion

Robotic surgery is becoming an increasingly important part of the urologist's armamentarium, with robotic techniques emerging as the standard of care throughout the scope of urological practice. However, this development requires caution. Success in robotic surgery requires extensive preparation on the part of the patient, urologist, and operating room team. Although existing work has begun to clarify some of these issues, further research is necessary to continually improve perioperative care. Such work will ensure that robotic surgery performed by urologists in the future will be done even more safely and effectively than today.

# Physiologic Considerations in Laparoscopic and Robotic Surgery

*Adam G. Kaplan & Michael N. Ferrandino*

*Division of Urologic Surgery, Duke University Medical Center, Durham, NC, USA*

## Introduction

Laparoscopic and robotic surgery challenge the patient with unique physiologic stresses. These stresses are primarily due to abdominal insufflation, but may be due to positioning requirements. Pneumoperitoneum, the result of abdominal insufflation, is considered necessary for visualization of the target organs, and may be maintained for prolonged periods of time. This can result in physiologic disturbances both during and after surgery as a result of increased abdominal pressure and absorption of the insufflated gas.

The introduction of laparoscopic cholecystectomy in 1990 and laparoscopic nephrectomy in 1991 proved pivotal for the future of laparoscopy, as for the first time solid organs could be removed with laparoscopic instrumentation [1, 2]. Following these advances, two major changes occurred in the field of laparoscopic surgery: first, the complexity and – consequently – the duration of minimally invasive surgical cases increased dramatically. Second, the patients selected for laparoscopic and robotic surgery covered an increasingly broader spectrum of disease states, with many patients having underlying cardiac and pulmonary comorbidities. As a result, the minimally invasive surgeon today must give significant consideration to the physiologic impact of prolonged pneumoperitoneum. While most patients tolerate the physiologic changes associated with laparoscopy well, there are occasional life-threatening complications as a result of the physiologic reaction to the laparoscopic environment.

Pneumoperitoneum and patient positioning required for laparoscopy have several well-understood physiologic effects which will be reviewed extensively in this chapter, along with the complications of pneumoperitoneum and consideration of methods of altering pneumoperitoneum that mitigate certain unwanted side effects.

## Impact of patient positioning

A number of patient positions are used during laparoscopy to more easily target the organ of interest. In urology, the lateral position is commonly used for upper urinary tract and retroperitoneal procedures; this position has little effect on hemodynamics unless there is extreme flexion or improper use of the kidney rest such that the vena cava is compressed, wherein venous return to the heart can be reduced [3]. The lateral position can lead to ventilation–perfusion mismatch and changes to pulmonary compliance for the dependent lung, as well as over-inflation and potential barotrauma to the nondependent lung.

During upper abdominal surgery, which is uncommon for urologic procedures, the patient can be placed head up (reverse Trendelenburg) to drop the bowel away. In most cases, this position demonstrates improved pulmonary mechanics [4–6]. However, this position also decreases cardiac output [7, 8] and can lead to profound hypotension and cerebral hypoperfusion, particularly in patients with pre-existing dysfunction of cerebral autoregulatory mechanisms, such as those with chronic hypertension, history of cerebrovascular accident, or carotid occlusive disease.

A position more commonly used by the urologist is Trendelenburg (head down), which can facilitate pelvic, lower urinary tract surgery such as radical

prostatectomy. This position increases cardiac output modestly [9–12]. Additionally, it restricts diaphragmatic movement and increases ventilation–perfusion mismatch [5, 13, 14]. As one might expect, the effects on cardiovascular and respiratory physiology are stronger with steeper head-down angles [15]. Table 78.1 compares the cardiovascular effects of the head-up and head-down positions.

## The gaseous medium: carbon dioxide and other insufflation agents

Today, the vast majority of laparoscopic and robotic cases are performed with carbon dioxide ($CO_2$) pneumoperitoneum. During the development of laparoscopy, the early cases were performed using oxygen and room air for insufflation [16]. These proved to be dangerous and quickly abandoned due to the significant potential for venous air embolism, intra-abdominal explosion, and combustion. Carbon dioxide was selected as it met a number of important criteria for the ideal gas for insufflation: it is readily available, inexpensive, noncombustible, rapidly soluble in plasma, and removed via respiration [17].

Due to the favorable properties of $CO_2$, it was adopted quickly. The rapid absorption of $CO_2$ decreased the chance of postoperative abdominal distention, and lowered the probability of developing a gas embolism. These same properties have dangers as well: they can lead to hypercapnia, hypercarbia, and cardiac dysrhythmia. While these sequelae are typically self-limiting, they can be problematic for patients with poor cardiopulmonary function and those with chronic obstructive pulmonary disease, as the minute ventilation may not be able to be increased sufficiently to compensate for the increased $CO_2$ absorption.

Other insufflation agents such as nitrogen dioxide ($N_2O$) and helium are possible alternatives in the select patient. While $N_2O$ came into favor in the 1970s and 1980s due to low cost, decreased peritoneal irritation, and fewer cardiovascular adverse effects compared to $CO_2$, case reports of intraoperative explosions due to its combustibility severely limited its use in the therapeutic setting [18–21]. In fact, it should be limited to cases where electrosurgical equipment is not needed. Helium, in contrast, is both inert and noncombustible. Rademaker et al. demonstrated favorable effects of helium on atrial partial pressure without hypercarbia or acidosis in a porcine model [22]. Helium insufflation may be useful in select patients with pulmonary disease who would not tolerate the hypercarbia associated with $CO_2$ insufflation [23]. The main drawback of helium is its low blood solubility, which may portend to a higher risk of gas embolism [24].

Considering the widespread, nearly exclusive use of $CO_2$ insufflation for laparoscopic procedures, the remainder of the chapter will focus on pneumoperitoneum with $CO_2$.

**Table 78.1** Effects of patient position on hemodynamic parameters compared to the supine position.

| Hemodynamic parameter | Head up | Head down |
|---|---|---|
| Heart rate | ↑ | ↓ |
| Mean arterial pressure | ↓ | ↑ |
| Systemic vascular resistance | ↑ | ↓ |
| Cardiac output | ↓ | ↑ |
| Intracranial pressure | ↓ | ↑ |

## Physiologic organ changes caused by insufflation with carbon dioxide

### Effect on the lungs

Pulmonary physiology is affected by a number of aspects during laparoscopic surgery. Patient size and the existence of underlying pulmonary pathophysiology certainly affect how the patient will respond to insufflation. The mechanical effects of pneumoperitoneum and the absorption of $CO_2$, however, are the main drivers of the physiologic changes seen during laparoscopy (Table 78.2).

As pneumoperitoneum increases the intra-abdominal pressure (IAP), it exerts a mechanical limitation to excursion of the diaphragm. This limitation results in decreased lung capacity and compliance, with eventual ventilation–perfusion mismatch and shunting [25, 26]. Consequently, there is an overall decrease in vital capacity, functional residual capacity, total lung volume, and

**Table 78.2** Respiratory effects of laparoscopy with intra-abdominal pressure of 10–20 mmHg.

| Respiratory parameter | Change |
|---|---|
| Chest wall mechanical resistance | ↑ |
| Peak inspiratory pressure | ↑ |
| Pulmonary compliance | ↓ |
| Alveolar dead space | ↔ or ↑ |
| Functional reserve capacity | ↓ |
| Forced vital capacity | ↓ |
| $FEV_1$ | ↓ |
| Peak expiratory flow | ↓ |

pulmonary compliance, alongside increases in peak inspiratory pressure [4, 5, 27]. These changes are exacerbated by obesity or other causes of pre-existing atelectasis and decreased lung volumes [4, 28].

Carbon dioxide has many properties, including its rapid solubility and quick absorption into the circulation, making it the ideal gas for insufflation. As such, it must be eliminated efficiently by the lungs. While normal $CO_2$ production in the average adult ranges from 150 to 200 ml/min [29, 30], the rate of $CO_2$ absorption during laparoscopy is 14–48 ml/min [31–33]. Adjustments must be made in minute ventilation by either increasing tidal volume or respiratory rate to mitigate the effects of increased blood levels of $CO_2$. If not corrected for, hypercarbia can lead to respiratory acidosis, which can depress cardiac function and cause arrhythmia. Subcutaneous emphysema, increased IAP, extraperitoneal insufflation, and prolonged surgery can also increase the rate of $CO_2$ absorption [34].

The minimally invasive surgeon must be aware of the compounding effects of $CO_2$ absorption over time, and how they can linger in the postoperative period. In a prospective study of changes in end-tidal $CO_2$ for healthy patients undergoing laparoscopic cholecystectomy, Meftahuzzaman et al. showed that significant alteration occurs 40 minutes after insufflation during cholecystectomy [35]. Many urologic cases can extend well past this period of time, and close monitoring of end-tidal $CO_2$ is imperative. Additionally, some degree of $CO_2$ is also sequestered in the skeletal system, which is the largest reservoir in the body, and it is eliminated slowly in the postoperative period. This can be particularly problematic for patients with pre-existing cardiopulmonary dysfunction, and these patients must be monitored closely [36].

## Effect on the heart and hemodynamics

Several hemodynamic effects are seen as a result of increased IAP, including decreased cardiac output, increased mean arterial pressures (MAP), increased systemic vascular resistance (SVR), and increased pulmonary vascular resistance (Table 78.3). At low insufflation pressures (<10 mmHg) there is an initial increase in venous return; this “auto-transfusion” causes the cardiac output and cardiac index to increase. Conversely, above 20 mmHg, venous return is hindered and there is a considerable decrease in cardiac output [37].

**Table 78.3** Hemodynamic effects of laparoscopy with intra-abdominal pressure of 10–20 mmHg.

| Hemodynamic parameter | Change |
|---|---|
| Central venous pressure | ↑ |
| Systemic vascular resistance | ↑ |
| Heart rate | ↑ |
| Mean arterial pressure | ↑ |
| Cardiac output | ↓ |

Patient factors can attenuate the cardiac response to pneumoperitoneum. Volume status is important as hypovolemic patients tend to have a more exaggerated drop in cardiac output in response to increased IAP. This was demonstrated by Ho et al. using a porcine model of acute hemorrhage [38]. Therefore generous volume loading can be recommended for patients undergoing laparoscopic procedures. Additionally, there is evidence that vagal stimulation from peritoneal distention can also decrease cardiac output. In fact, pneumoperitoneum causes excessive stretching of the vagal nerve endings, which are richly distributed throughout the abdominal cavity, which can lead to bradycardia [39]. Patient positioning, particularly for deep pelvic surgery, also has a significant impact. The Trendelenburg position decreases venous return. This exacerbates the effect of increased IAP, which further decreases venous return due to caval compression [40] and increased venous resistance [41, 42]. Of note, the opposite effect occurs with reverse Trendelenburg.

Increased SVR and MAP are also attributable to the sympathoadrenal effects of increased IAP and $CO_2$ insufflation [43]. There is increased catecholamine production, presumably from both surgical stress and directly from the increased IAP. Early hypercarbia may also exacerbate this sympathomimetic effect; however, as hypercarbia progresses and acidosis becomes more profound, a cardiodepresent effect predominates. The renin-angiotensin system and vasopression are also postulated to be contributors to the increases in SVR [44–48]. There is a rapid increase in plasma renin activity during induction of pneumoperitoneum, and increased plasma renin activity positively correlates with MAP [49–51]. Additionally there is a significant increase in anti-diuretic hormone (ADH), which controls arterial blood pressure via receptors in vascular smooth muscle; this can provoke intense vasoconstriction and likely plays a key role in regulating hemodynamics during laparoscopy [46, 48].

A recent study by Rosendal et al. [52] sought to determine changes in preload, afterload, and cardiac function in the different phases of robotic prostatectomy, including induction of anesthesia, initiation of pneumoperitoneum, immediately after a 45° head-down tilt, 15 minutes later into the head-down tilt, after release of pneumoperitoneum, and 5 minutes after returning to a horizontal position. Central venous pressure increased threefold from baseline after induction of anesthesia, but no other preload parameters showed overload or demand. There was no change in cardiac contractility over time. Afterload increased significantly during $CO_2$ pneumoperitoneum and decreased compared with baseline after the release of pneumoperitoneum at the end of the case. Heart rate and cardiac index increased significantly during robot-assisted laparoscopic prostatectomy [52].

### Effect on the kidneys

Oliguria is a well-characterized side effect of sustained pneumoperitoneum. This is important to know, as relying on urine output alone as an indicator of fluid status can lead to fluid overload in overzealous hands. There are several possible causes of oliguria in this setting, which appear to occur at an IAP around 15 mmHg [53]. It is well documented that elevated IAP causes significant renal hypoxia and decreased renal blood flow [54]. One theory as to why this occurs is that there is a Page kidney effect, whereby applying renal parenchymal compression causes a decrease in urine output, glomerular filtration rate (GFR), and effective renal blood flow. Razvi et al. proved this experimentally by placing a pressure cuff at 15 mmHg on the left kidney of canines, thereby causing overall urine output to decrease [55]. Using a porcine model, Chiu et al. demonstrated that pneumoperitoneum-induced oliguria may also be due to increased serum aldosterone levels [56].

Elevated IAPs are thought to stimulate endogenous catecholamine release, another potential contributor to oliguria. Circulating levels of endothelin, a catecholamine, is increased in response to pneumoperitoneum [57]. Studies of unilateral renal vein compression in a rat model and a canine model showed decrease in GFR and urine osmotic pressure in both kidneys. In each case, circulating endothelin increased [53, 58].

Vasopressin has also been implicated as a contributor to oliguria. Krisch et al. demonstrated in a rat model that using vasopressin antagonists during periods of increased IAP improved renal function compared to control [59].

Other possible causes of oliguria have been studied and disproven. The decreased cardiac output seen with increased IAP is unlikely to affect renal output; studies have shown that normalization of the cardiac output with fluid resuscitation does not lead to increased urine output [60, 61]. Ureteral obstruction, similarly, is unlikely to contribute significantly. Patients with ureteral stents, which presumably remain unobstructed, do not have increased urine output [62]. Additionally, animal imaging studies with intra-operative urography show no evidence of ureteral obstruction during pneumoperitoneum [56].

Importantly, the renal effects from increased IAPs tend to subside in the immediate postoperative period in healthy patients with normal renal function [63]; however, those with pre-existing renal dysfunction may experience longer delays to return to baseline GFR [64]. A rabbit model of severe hydronephrosis showed that obstructed kidneys were more likely to suffer acute kidney injury when exposed to pneumoperitoneum [65]. While pneumoperitoneum was certainly feasible in rats with impaired baseline renal function, it appeared worse for those with acute kidney injury than chronic renal insufficiency [66]. Patients with significant cardiovascular dysfunction such as decompensated congestive heart failure also appear to be more susceptible to the adverse renal effects of pneumoperitoneum [67].

### Effect on the brain

Changes in cerebral blood flow during laparoscopy can occur even at a mildly increased IAP, and are due to several factors: cardiovascular changes, alterations in $P_aCO_2$, patient positioning, and the increased intra-abdominal and intra-thoracic pressures. Rosenthal et al. demonstrated increases in intracranial pressures (ICPs) and IAPs above 8 mmHg in a large-animal model [68]. This is thought to be due to compression of the vena cava, which increases central venous pressures and decreases drainage from the central nervous system.

Studies have also shown that cerebral blood flow velocity increases due to the increase in $P_aCO_2$ that results from $CO_2$ pneumoperitoneum [69]. Additionally, hypercapnia causes cerebral vascular vasodilation which increases ICP. This effect can be mitigated by hyperventilation.

A retrospective review of measured ICPs in patients undergoing laparoscopic ventriculoperitoneal shunt placement confirmed a correlation between IAP and ICP. The maximum recorded ICP was 25 mmHg, which can be dangerous for certain patients, particularly those with increased ICP at baseline or head trauma [70]. A study of patients undergoing robotic prostatectomy in steep Trendelenburg quantified the increase in ICP in these patients with ultrasonic evaluation of optic nerve sheath diameter, a surrogate measurement for ICP. This found a 12.5% increase during $CO_2$ pneumoperitoneum. Of note, three of the 20 patients studied showed ICPs above 20 mmHg without a deterioration of cerebral oxygen saturation or any neurologic complications [71].

### The stress response to insufflation

Several studies have compared open versus laparoscopic procedures in regards to the associated stress response elicited in the patient. Laparoscopy is generally shown to produce a decreased stress response compared to open procedures, but these results are often mixed.

Laparoscopy certainly does increase the MAP and SVR compared to open surgery. This increase in arterial pressure, in turn, increases ADH, plasma renin, and aldosterone levels [49]. Additionally, cortisol, human growth hormone, vasopressin, and other endogenous cathecholamines such as epinephrine and norepinephrine have been associated with an increase in IAP [45].

However, in a series of studies, acute-phase reactants typically seen during surgery, such as C-reactive protein and interleukin-6, are significantly lower as compared to open procedures [49, 72, 73]. There is also less hyperglycemia and leukocytosis seen [72, 73]. Notably, a recent study of patients undergoing laparoscopic adrenalectomy at varying IAPs showed that significantly higher levels of acute phase reactants were seen in patients given standard insufflation (12–14 mmHg) versus low pressure pneumoperitoneum (6–8 mmg) [74]. Such a difference was not seen in a prospective study by Landman et al., which concluded that stress factors, inflammatory markers, and other markers of immune activity were not statistically different between patients undergoing open versus laparoscopic nephrectomy. They postulate that the extent and length of surgery required for laparoscopic nephrectomy is often greater than laparoscopic cholecystectomy and that above a certain threshold (for laparoscopic or open surgery) the immune response reaches an upper limit [75].

Other markers of inflammatory response also point to the superiority of laparoscopy to standard open surgery. To demonstrate this, Dalgic et al. experimentally performed cecal-peritoneal abrasions in rats using either a standard open technique or laparoscopy with $CO_2$ pneumoperitoneum. There was a decreased inflammatory response seen, as well as decreased adhesion formation in the laparoscopy group [76].

Lastly, laparoscopic surgery, by virtue of causing tissue injury, activates the coagulation and fibrinolytic pathways, another part of the inflammatory cascade. In a prospective randomized trial of patients undergoing laparoscopic versus open cholecystectomy, Tsiminikakis et al. showed significantly less activation of the clotting system in laparoscopic surgery compared to open surgery [77].

## Complications of obtaining and maintaining pneumoperitoneum

While a number of physiologic changes occur due to pneumoperitoneum itself, some complications can occur during the establishment of pneumoperitoneum. A misplaced Veress needle or Trocar with subsequent insufflation can cause a number of potential problems.

Subcutaneous emphysema is the most common result of an improperly placed Veress needle or Trocar, but can also be due to excessive IAPs, malfunctioning equipment, or leaks around a laparoscopic port placed with an open technique. While it is usually harmless, it can in some circumstances lead to hypercarbia [78–80]. In rare cases, it can enter the pleural or extrapleural space, the mediastinum, or the pericardium. Subcutaneous, retroperitoneal, or extraperitoneal gas, unlike intraperitoneal gas, is not limited by the peritoneum and can therefore traverse a variety of tissue planes: for example, $CO_2$ can dissect along the great vessels or from the anterior neck into the mediastinum and, from there, rupture into the pericardium or travel along the pulmonary vessels into the pleural space [81]. Several early case reports describe this to result in pneumopericardium [82–84] or pneumothorax [81, 84, 85]. Most small pneumothoraces can be managed conservatively in the absence of hemodynamic or respiratory compromise, but large or symptomatic pneumothoraces may require treatment with needle aspiration or, rarely, chest tube placement.

Gas embolism is a potentially fatal complication in which the Veress needle is inadvertently placed into a vein, thereby injecting gas directly into the venous system. The incidence is estimated between 0.002 and 0.08% [37]. This complication can also arise from venous injury during the laparoscopic procedure [86, 87]. The gas bubble travels to the right heart and lodges in the atrium or pulmonary arterial system. The result can be catastrophic as the gas lock can obstruct venous return to the atrium resulting in a sharp drop in cardiac output. Alternatively, it could obstruct the pulmonary blood flow causing pulmonary hypertension and right heart failure. The diagnosis of gas embolism is suggested by dramatic, sudden cyanosis, hypoxia, hypercarbia, arrhythmia, or hypotension during insufflation or after venotomy. The pathognomonic "mill wheel" murmur may also be present and widening of the QRS complex with a right heart strain pattern on ECG can also be seen. Capnography may be useful in early diagnosis of gas embolism [88]. The most sensitive detector of gas embolism is transesophageal echocardiography, which can detect a $CO_2$ embolus as small as 0.02 ml [86, 87, 89]. In experimental animal cases of gas embolization caused by direct venotomy, the degree of embolization correlated with the decrease in central venous pressure due to blood loss or distal venous compression, the duration and amount of manipulation of the venotomy and the intraperitoneal pressure [86]. As such, in the event of significant venous injury during laparoscopy it is important to maintain intravascular volume and occlude the site of bleeding directly.

Treatment of gas embolism includes immediate desufflation, initiation of 100% inspired oxygen, and resuscitative measures. The patient should be turned laterally with the right side up and head down; this position prevents further air from entering the pulmonary circulation and the air bubble can be aspirated with a central venous catheter in the right atrium.

Cardiac dysrhythmias can occur as a result of the establishment and maintenance of pneumoperitoneum. Two studies early in the development of laparoscopy reported several anomalies [90, 91]. Bradycardia occurred shortly after initiation of $CO_2$ insufflation in several patients, thought to be due to reflex vagal stimulation from stretching of the peritoneum. Ventricular arrhythmias were also reported thought to be due to ventilator insufficiency. Extraventricular beats were also seen in 17% of patients with $CO_2$ pneumoperitoneum compared to 4% with $N_2O$ pneumoperitoneum, which may point to hypercarbia as a cause [91].

## Considerations with obesity

Obesity, defined as having a body mass index >30 $kg/m^2$, continues to increase in prevalence in the United States, now affecting over 30% of patients. Laparoscopy and robotic surgery may be more suitable than open surgery for many of these patients, but they carry unique risks and physiologic challenges from pneumoperitoneum. These patients tend to have a host of other comorbidities including diabetes mellitus, hypertension, hypercholesterolemia, arthritis, and asthma [92].

Obesity impacts respiratory mechanics, such that morbidly obese patients have reduced functional residual capacity, lower chest wall compliance, and increased carbon dioxide production at baseline [27, 28]. Pneumoperitoneum will reduce compliance to a greater degree in obese patients compared with normal-weight control subjects. Obese patients required 15% higher minute ventilation to maintain normocarbia in the supine position. Interestingly, changing to a Trendelenburg position had little impact on overall outcome, suggesting that obese patients who tolerate the induction of anesthesia and pneumoperitoneum in the supine position will likely tolerate the Trendelenburg position [27, 28]. This paradoxical finding was thought to be due the mechanical effects of pneumoperitoneum, which opposed the gravitational shift of abdominal contents.

A "tilt test" has been found to be helpful in many cases. Once the patient is intubated and positioned, the patient can be placed in a steep Trendelenburg for 2–5 minutes and the cardiac and respiratory status can be monitored. If tolerated, meaning the patient remains normotensive with inspiratory pressures at 30–40 mmHg, the abdomen can then be insufflated and monitored. If the patient continues to tolerate insufflation, they are likely to tolerate the remainder of the laparoscopic procedure [93].

## Modifying pneumoperitoneum

A number of modifications to standard $CO_2$ pneumoperitoneum have been investigated, in the hope of mitigating the adverse effects of increased IAP and the absorption of insufflant. Low-pressure or gasless laparoscopy has been extensively investigated, and there are now commercially available abdominal wall elevators that are secured to the operating table (Laparolift, Origin Medsystems, Menlo Park, CA, USA). A number of different devices were created and employed to do a similar task: elevate the anterior abdominal wall away from the intra-abdominal organs, thereby creating a working space and eliminating the need for insufflation. This has allowed for completion of numerous laparoscopic procedures at pneumoperitoneum pressures down to 4 mmHg, which may be preferable for patients who would otherwise be unable to tolerate increased IAPs or hypercapnia [94–96]. These wall-lifting methods have been shown to reduce stress response compared to standard pneumoperitoneum [97]. They have proven to be safe, to preserve pulmonary function, and in some cases decrease hospital stay [98]. While the low-pressure environment certainly limits surgeon comfort, it has been shown to decrease postoperative pain [99].

Others have looked at altering the temperature of the gaseous medium but reports on the physiologic benefits are mixed. A study compared insufflation with warm $CO_2$ to insufflation with $CO_2$ at room temperature, finding that warm $CO_2$ lead to higher core temperatures, increased urine output, and increased cardiac index [100]. This is thought to be due to regional vasodilatation of the renal vasculature which restores both renal blood flow and urine output. These improvements can be of particular benefit to those patients with renal dysfunction. Fluid management becomes more predictable with more reliable urine output

Other perceived benefits of warmed and humidified insufflant have not panned out. While one multicenter double-blind study randomized controlled trial showed no attenuation of the early inflammatory cytokine response [101], another study of patients undergoing laparoscopic cholecystectomy with warmed versus room temperature insufflation showed improvement in core temperature by 0.32 °C, but no major clinically relevant differences were seen [102]. In fact, a Cochrane review of the subject concluded that heated gas insufflation, with or without humidification, has minimal benefit on patient outcomes [103].

AirSeal® (Surgiquest, CT, USA) is a novel valve-free and membrane-free insufflation and Trocar system that enables a stable pneumoperitoneum with continuous smoke evacuation and $CO_2$ recirculation during laparoscopic surgery. It responds immediately to slight changes in IAP, and may be associated with reduced $CO_2$ use and absorption. Horstmann et al. prospectively compared the AirSeal Trocar system to a standard Versaport Plus V2 Trocar for assisting robotic radical prostatectomy. While there was no significant decrease in operative time, blood loss, camera cleaning, or overall $CO_2$ consumption, the AirSeal Trocar provided a more stable pneumoperitoneum with only one episode of pressure loss during 19 cases, as compared to 38 pressure-loss episodes in 17 cases performed with the standard port [104]. Further clinical studies are underway to characterize the potential benefits of the system [105].

## Conclusion

The physiologic effects of laparoscopy and robotic surgery are the result of patient positioning and the effects of insufflation of the abdomen. Pneumoperitoneum is most frequently created with carbon dioxide gas, as it is inexpensive, colorless, odorless, non-flammable, and rapidly eliminated from systemic circulation. It creates a number of physiologic challenges due to increased IAP and the absorption of $CO_2$, for the cardiovascular, pulmonary, renal, brain, and endocrine systems. Complications such as subcutaneous emphysema, cardiac arrhythmia, and gas embolism may arise. In addition, special considerations for the obese patient and those with cardiopulmonary compromise must be made. While studies to improve laparoscopy and the effects of pneumoperitoneum continue, the effects of pneumoperitoneum are generally well tolerated.

# Anesthetic Management During Laparoscopic/Robotic Surgery

*Judith Aronsohn, Oonagh Dowling, & Greg Palleschi*

*Department of Anesthesiology, Zucker School of Medicine at Hofstra/Northwell, New York, NY, USA*

## Introduction

Minimally invasive surgical techniques are rapidly becoming the accepted standard of care worldwide for many procedures performed by urologists. Laparoscopy is being increasingly utilized in nephrectomies (radical, partial, and living donor), nephroureterectomy, pyeloplasty, radical prostatectomy, pelvic lymph node dissection, varicocelectomy, and total cystectomy with ileal conduit formation. Significant advantages include decreased hospital length of stay, reduced blood loss, and fewer complications including in-hospital deaths when compared to open surgery for many procedures [1, 2]. Additional benefits include less postoperative pain, lower narcotic requirements, improved cosmetic results, and earlier return to normal activity. Robotic technology offers a three-dimensional view of anatomic structures, superior precision, and dexterity, and may be associated with a significantly faster learning curve than conventional laparoscopy [3, 4]. The anesthesiologist should be aware of the surgeon's expertise in this area as it has a profound influence on the postoperative management of the patient.

## Anesthetic considerations

The anesthesiologist is presented with a number of perioperative challenges during minimally invasive urologic surgery, and anesthetic management is guided by surgical complexity, patient positioning, duration of procedure, potential for blood loss, and the patient's baseline status. Patient access may be severely limited during robotic surgeries, and the physiologic consequences of extreme positioning and pneumoperitoneum may not be well tolerated. Rapid port removal and robot disengagement may become necessary during the case and requires clear communication with operating room personnel familiar with the equipment and operating room environment. Teamwork and effective communication are essential to assure optimal patient outcomes.

## Preoperative assessment

Patients scheduled for elective procedures should be evaluated in a preoperative clinic to ascertain patient specific and procedural risk factors, facilitate a perioperative management plan, and manage comorbid conditions. Previous studies show that visiting an anesthesiologist-led preadmission testing clinic before surgery can reduce preoperative consultations, decrease surgical cancellations, reduce costs associated with unnecessary testing, and reduce in-hospital mortality [5–7]. A complete history and physical exam should be performed with a focus on cardiopulmonary function and potential airway problems. Any pre-existing neuropathies should be investigated and documented to avoid being misdiagnosed as a complication of surgical positioning. More extensive preoperative testing should be guided by the patient's functional capacity, comorbidities, type of procedure, and surgical expertise. Current American College of Cardiology/American Heart Association guidelines should be followed for patients with known or suspected cardiac disease [8].

There are few, if any, agreed-upon absolute contraindications to laparoscopic surgery, and its safety in high-risk patients has been documented extensively [9–12]. Contraindications include patient conditions that preclude major surgery by any approach, such as severe decompensated cardiopulmonary disease or uncontrolled bleeding diatheses [13]. Patient-specific factors

that may lead to procedural difficulties and prolonged surgery include morbid obesity, adhesions, and prior radiation therapy [14]. Patients considered high risk should be counseled in the rare event that a planned laparoscopic procedure must be converted to an open procedure.

## Anesthetic management

The goal of anesthetic management is to provide optimal and safe surgical conditions while managing the physiologic and hemodynamic responses associated with laparoscopic surgery. General anesthesia with a secured airway and controlled ventilation is the most common technique used during laparoscopy. Although supraglottic airway devices have been used in laparoscopic cholecystectomies and short laparoscopic gynecologic procedures, their use in longer procedures requiring steep Trendelenburg position has not been sufficiently studied to recommend [15, 16]. Induction of general anesthesia and endotracheal intubation are usually accomplished with intravenous administration of propofol and an intermediate-acting muscle relaxant. Etomidate and ketamine may be used in patients who cannot tolerate the hemodynamic effects of propofol. The endotracheal tube should be secured immediately after the cuff passes the vocal cords to prevent possible right endobronchial migration after abdominal insufflation [15, 17, 18]. Carbon dioxide pneumoperitoneum with Trendelenburg position increases endotracheal tube cuff pressure, leading to significant postoperative patient discomfort [19]. This can be avoided by periodically measuring the cuff pressure during the case. Anesthesia can be maintained with a volatile anesthetic combined with an opioid or total intravenous anesthesia (TIVA) with propofol. TIVA with propofol has been shown to decrease the incidence of early postoperative nausea and vomiting (PONV) in patients undergoing robot-assisted radical prostatectomy (RALP) [20]. Complete muscle relaxation with controlled ventilation is recommended to provide optimal surgical conditions and prevent hypercapnia. Patient movement must be avoided at all costs when incorporating robot assistance. Minute ventilation may need to be increased as much as 30% to maintain normal $P_aCO_2$ levels [21]. Oxygenation and respiratory mechanics are similar whether ventilation is volume- or pressure-controlled during laparoscopy, even in morbidly obese patients [22, 23]. Constant application of 5 $cmH_2O$ of positive end-expiratory pressure (PEEP) effectively maintains $P_aO_2$ levels during prolonged pneumoperitoneum [24] and, combined with low tidal volumes (6 ml/kg), may decrease postoperative pulmonary complications [25]. In addition, application of PEEP is associated with decreased blood loss during RALP [26]. The use of nitrous oxide, although not contraindicated, is frequently avoided due to its ability to cause bowel distention and contribute to PONV. Additionally, it can worsen the effects of air embolism and pneumothorax [27, 28].

Standard patient monitoring should include electrocardiogram, noninvasive arterial blood pressure, pulse oximetry, capnography, peripheral nerve stimulator, airway pressure, and temperature probe. Invasive blood pressure monitoring may be indicated in patients with significant cardiopulmonary disease, particularly when access to the upper extremities is restricted. Frequent blood gas analysis may be necessary in patients with increased dead space ventilation (i.e. chronic obstructive pulmonary disease, asthma, acute respiratory distress syndrome), as end-tidal $CO_2$ is an unreliable estimate of $P_aCO_2$ in these conditions. Two large-bore intravenous lines should be placed when significant intraoperative blood loss is anticipated or patient position precludes later placement should additional access become necessary. All lines and monitors should be rechecked after the patient is positioned to confirm they are functioning properly. A central line is rarely indicated. A fluid warmer and warming blanket is used to mitigate the effect of cold insufflated gasses on core body temperature. Even mild hypothermia is associated with adverse cardiac events, bleeding, and impaired wound healing [29].

Neuraxial techniques have been utilized successfully in a number of laparoscopic procedures, including transperitoneal nephrectomy, ureterolithotomy, and nephrolithotomy [30–32]. Drawbacks associated with the use of spinal and epidural anesthetics include inadequate abdominal relaxation, shoulder tip pain, urinary retention, and respiratory insufficiency secondary to carbon dioxide pneumoperitoneum. Benefits include less PONV and decreased need for postoperative analgesics. Laparoscopic cholecystectomy under epidural anesthesia has been successfully performed in high-risk chronic obstructive pulmonary disease patients classified as “too sick” for general anesthesia and endotracheal intubation [33].

Meticulous attention to patient positioning is imperative to prevent nerve injury and other complications. Positioning is even more critical when the robot is employed because the camera system and working arms must be accommodated. All pressure points and dependent areas must be padded and avoidance of extreme flexion, extension, and abduction should be followed to help minimize neuromuscular injuries. The back of the head should be padded and the face protected with foam pads or a mayo stand to prevent contact with the robot camera. If foam pads are used over the face, they should be easily removable in case of an airway emergency. When steep Trendelenburg position is required, egg-crate foam or surgical gel pads placed directly under the patient are commonly used to prevent cephalad migration on the operating room table. Shoulder straps, shoulder braces, and head rests are associated with neuromuscular injuries, particularly brachial plexus injury [34]. Chest straps are often utilized, but may decrease chest wall compliance. Some authors recommend placement of a throat pack to prevent gastric reflux through the lacrimal ducts with resulting chemical burns to the cornea [35]. For patients in the lateral decubitus position, a chest roll placed under the dependent hemithorax relieves tension on the brachial plexus by preventing compression of the axilla and shoulder. If an upper or double arm board is used, it must be properly set to prevent compression of the radial nerve at the posterior aspect of the humerus [36]. Excessive pressure on the dependent ear and eye should be avoided. Adhesive eye shields or Tegaderms can be used for eye protection.

## Fluid management

Although evaporative losses and fluid shifts are significantly reduced during laparoscopic surgery compared to open procedures, the ideal strategy for fluid replacement remains elusive. Patient condition, type of procedure, and patient position during the case help inform intraoperative fluid replacement therapy. Heart rate, blood pressure, urine output, and central venous pressure are not reliable measures of volume status. Pneumoperitoneum and Trendelenburg position make goal-directed fluid therapy indices difficult to interpret, and no single hemodynamic goal or monitoring method has been accepted across the literature [37, 38]. Restrictive fluid regimes have been associated with longer hospital length of stay and delayed postoperative wound healing in patients undergoing laparoscopic surgery, while fluid loading has successfully decreased rates of PONV [39, 40]. Conservative intravenous fluid administration during RALP decreases the amount of urine obscuring the operative field and may also reduce postoperative laryngeal edema resulting from prolonged Trendelenburg position [34].

## Physiologic changes

The physiologic changes that accompany laparoscopic surgery are well tolerated in healthy (American Society of Anesthesiologists [ASA] grade I or II) patients. They are produced by the interaction of several factors, including pneumoperitoneum, carbon dioxide absorption, patient position,surgical procedure, and the patient's baseline cardiopulmonary status.

### Pneumoperitoneum

Pneumoperitoneum has profound effects on the cardiovascular, cerebrovascular, and respiratory systems. Displacement of the diaphragm cephalad decreases tidal volume, pulmonary compliance, and functional residual capacity. Peak inspiratory pressure and plateau pressures increase secondary to atelectasis and narrowing of the large airways. Moderate Trendelenburg position does not seem to affect these changes, even in the morbidly obese [41, 42]. Steeper levels of Trendelenburg may worsen lung compliance [43]. Atelectasis may be more prominent in older people due to increased closing capacity with age. Strategies to mitigate the effects of these changes are discussed under Anesthetic management. Cardiovascular changes associated with pneumoperitoneum are related to the degree of increased intra-abdominal pressure and position of the patient. Intra-abdominal pressures up to 12 mmHg can cause an initial rise in cardiac output by increasing preload as blood volume is forced from the splanchnic vessels into the inferior vena cava. When intra-abdominal pressure rises above 15 mmHg, reductions in preload and cardiac output can be seen secondary to caval compression. A rise in systemic vascular resistance (SVR) is due to many factors, including compression of the arterial vasculature, the release of catecholamines and vasopressin, and activation of the renin-angiotension system. Odeberg et al. reported a 58% increase in central venous pressure and a 32% increase in pulmonary capillary wedge pressure in healthy patients after abdominal insufflation in the horizontal position when intra-abdominal pressure was maintained between 11 and 13 mmHg. Cardiac filling pressures were further increased by 40% when patients were placed in the Trendelenburg position [44].

Lestar and colleagues found a threefold increase in central venous pressure in ASA grade I–II patients undergoing RALP in 45° Trendelenburg position with an intra-abdominal pressure of 11–12 mmHg. Mean pulmonary artery pressure and pulmonary capillary wedge pressure increased twofold, but cardiac performance was unaffected [45]. It should be noted that the effects of intra-abdominal hypertension may be exaggerated in hypovolemic patients or those with cardiovascular disease, particularly if the reverse Trendelenburg position is used. Severe reflex bradycardia resulting from stretching of the peritoneum during insufflation has also been reported [46].

Pneumoperitoneum decreases renal blood flow, although the clinical significance of this is unknown [47]. This decrease in blood flow is pressure dependent and intensified by the reverse Trendelenburg position. Mechanical compression of the renal vein and increased secretion of antidiuetic hormone decrease glomerular filtration and urine output. The renin-angiotensin-aldosterone system is activated, leading to further reductions in renal blood flow. Pneumoperitoneum-associated hemodynamic changes in kidney donors can negatively affect transplanted kidney function [48]. Suggested measures to protect renal function, particularly during laparoscopic live donor nephrectomy, include maintaining a positive intravascular fluid balance and limiting intra-abdominal pressure to a maximum of 12 mmHg [49]. Ureteral obstruction due to mechanical pressure has not been shown to play a significant role in renal dysfunction associated with pneumoperitoneum [50].

### Carbon dioxide absorption

Carbon dioxide ($CO_2$) is the gas most commonly used for abdominal insufflation during laparoscopy because it is highly soluble, inexpensive, nontoxic, nonflammable, and easily eliminated through the lungs. Its high solubility makes it less likely than air to cause clinically significant gas embolus. $CO_2$ is systemically absorbed during laparoscopy, potentially causing respiratory acidosis. During carbon dioxide pneumoperitoneum, end-tidal $CO_2$ progressively increases, reaching a plateau after 40 minutes if minute ventilation is kept constant [51]. Thereafter, $CO_2$ accumulates in the body and $CO_2$ output may be increased for up to 30 minutes after abdominal decompression [52]. Factors contributing to a higher degree of $CO_2$ absorption include higher insufflation pressure, longer insufflation time, and subcutaneous emphysema [53–56]. Hypercarbia can cause arrhythmias and contribute to increased SVR during laparoscopy. Excess $CO_2$ is easily eliminated in healthy patients by increasing minute ventilation. However, hypercarbia can induce pulmonary vasoconstriction that may be poorly tolerated in patients with pulmonary hypertension. Alternatively, permissive hypercarbia causes vasodilatation and shifts the oxyhemoglobin dissociation curve to the right, improving tissue perfusion and oxygen delivery [57]. Elevated $P_aCO_2$ has also been shown to reduce shunting by increasing blood flow to noncollapsed lung regions [58].

### Patient position

The most common positions for laparoscopic and robotic urological procedures are the low dorsal lithotomy with steep (35°) Trendelenburg position, followed by the lateral jackknife decubitus position. Neurological complications after prolonged periods of steep Trendelenburg have been reported [59]. Schramm and colleagues used transcranial Doppler to investigate the time course of cerebral autoregulation during RALP. Their findings suggest a slow deterioration of cerebral autoregulation during extreme Trendelenburg position combined with pneumoperitoneum [60]. Kim et al. used optic nerve sheath diameter to assess intracranial pressure in 20 patients undergoing RALP. In 15% of patients optic nerve sheath diameter increased to levels equivalent to an intracranial pressure >20 mmHg. No postoperative neurological complications were noted in their study [61]. Although not strictly contraindicated, laparoscopic surgery in Trendelenburg position has been safely performed in patients with ventriculoperitoneal shunt [62].

Intraocular pressure (IOP) has been shown to increase significantly over time in patients undergoing RALP with steep Trendelenburg. However, no perioperative visual loss has been attributed to steep Trendelenburg positioning alone in patients without pre-existing ocular disease [63, 64]. There is at least one case report of a patient with primary open-angle glaucoma undergoing RALP. The IOP was measured after induction of general anesthesia and every 15 minutes thereafter. Increased IOP was treated with intravenous acetazolamide and mannitol. The patient's visual acuity postoperatively remained unchanged [65]. Preoperative consultation with the treating ophthalmologist is recommended for patients with glaucoma as intraoperative treatment for increased IOP may be warranted.

Some degree of lateral positioning is commonly used for kidney surgery depending on the surgical approach, i.e. transperitoneal or retroperitoneal. Advantages to the retroperitoneal approach include less need for visceral retraction and lack of peritoneal irritation from insufflated carbon dioxide. Transperitoneal is associated with a larger increase in peak inspiratory pressure and plateau pressure when compared to retroperitoneal [66]. This may be attributed to greater interference to diaphragmatic excursion when the transperitoneal is used. Which approach results in less $CO_2$ accumulation is the subject of debate. Bannenberg et al. found arterial $CO_2$ levels increased significantly more during intraperitoneal insufflation compared to extraperitoneal insufflation in piglets [67]. This is presumably due to the increased diaphragmatic surface area exposed to $CO_2$. Streich et al. and Mullet et al. found retroperitoneal carbon dioxide insufflation causes more carbon dioxide absorption than intraperitoneal insufflation [68, 69], and Ng et al. found no difference in carbon dioxide absorption when comparing the retroperitoneal to the transperitoneal approach [70].

## Enhanced recovery after surgery

Enhanced recovery programs (ERPs) have been utilized in urology for both open and minimally invasive procedures, but adoption has been slow. ERPs are increasingly being implemented to improve patient outcomes and reduce healthcare costs through standardized, evidence-based perioperative care. Minimally invasive surgery alone represents a major opportunity to enhance recovery and reduce morbidity, especially when combined with other aspects of an ERP. Although most of the literature on this topic is derived from colorectal surgery, many elements have been effectively applied to ERPs in other specialties. It should be noted that the number and type of ERP elements varies widely across the literature and the impact of any individual element on outcomes is not clear. Successful ERPs require a multidisciplinary, team-based approach and coordination of evidence-based care throughout the perioperative continuum. Anesthesiologists are responsible for delivering many elements in an ERP, highlighting the importance of their commitment to this process. Collaboration between the surgeon and anesthesiologist is essential for an ERP to be effective and sustainable. An ERP begins when surgery is scheduled and ends when the patient returns to their preoperative functional status. ERP interventions can be classified as preoperative, intraoperative, and postoperative. The anesthesiologist plays an important role in the shared decision-making for many of these interventions, including:

1) identification and optimization of patient's comorbid conditions before surgery,
2) utilizing opioid-sparing anesthetic techniques, including regional blocks, that minimize postoperative pain and allow for rapid recovery,
3) aggressive prophylaxis and treatment of PONV,
4) utilizing effective pre-emptive analgesics and an opioid-sparing multimodal strategy for postoperative pain management,
5) providing goal-directed or zero-balance fluid therapy perioperatively (when evidence-based).

Common elements found in many enhanced-recovery or "fast-track" protocols for gastrointestinal and urologic surgery are listed in Table 79.1. Inclusion, modification, and/or elimination of elements in a protocol should be evidence-based and procedure-specific.

Magheli et al. studied 50 patients undergoing laparoscopic radical prostatectomy randomized to conventional or enhanced recovery fast-track care. Patients in the fast-track group mobilized earlier, had lower pain scores and a decreased overall complication rate, and were discharged home earlier than patients in the conventional group. Postoperative pain in the fast-track group was managed with a COX-2 inhibitor [71]. Dudderidge and colleagues reduced intraoperative and postoperative opioid use by incorporating a pre-emptive transversus abdominis plane (TAP) block as part of a standardized anesthetic technique into their care pathway for laparoscopic radical prostatectomy. Some 78% of patients who received a TAP block were discharged home on postoperative day 1, and 7% went home on the evening of surgery [72]. Enhanced recovery protocols have been utilized in robot-assisted laparoscopic cystectomy and laparoscopic nephrectomy with promising results [73, 74]. More studies are needed in minimally invasive surgery as part of the enhanced recovery paradigm to assess and clarify its influence on patient outcomes and cost effectiveness.

## Postoperative pain management

Minimally invasive laparoscopic procedures are known to cause less pain than open procedures. However, characteristics of the laparoscopic approach such as insufflation of the abdomen with $CO_2$ can create unique postoperative pain management challenges. Postoperative pain associated with robotic/laparoscopic surgery is caused by tissue trauma at port incision, peritoneal distention, and diaphragmatic irritation that leads to referred shoulder pain. Although there are no procedure-specific guidelines for pain management in urologic surgery the goal is to provide adequate analgesia while curtailing the administration of systemic opioids. Opioids are associated with a

**Table 79.1** Common elements of enhanced recovery protocols.

| Preoperative | Intraoperative | Postoperative |
|---|---|---|
| Patient education and counseling<br>Preoperative risk assessment and optimization (hypertension, diabetes, anemia)<br>Carbohydrate drink (clear) night before and 2 hours before surgery<br>Preoperative administration of non-narcotic analgesics<br>Avoidance of mechanical bowel preparation<br>Alcohol and tobacco abstinence<br>Thromboembolic prophylaxis | Fluid optimization to maintain euvolemia<br>Fluid warmer and warming blanket to maintain normothermia<br>Minimally invasive surgery<br>Pre-incision regional block/local anesthetic infiltration<br>Opioid-sparing techniques<br>Prophylactic antiemetics, antimicrobial prophylaxis | Multimodal, opioid-sparing analgesia<br>Antiemetics<br>Early routine mobilization<br>Early enteral nutrition<br>Avoidance of nasogastric tubes<br>Avoidance of peritoneal drains<br>Early removal of catheters<br>Rehabilitation plan |

number of undesirable side effects, including nausea, vomiting, pruritus, urinary retention, respiratory depression, and delayed return of bowel function. For this reason, opioid-sparing multimodal analgesic techniques are increasingly being utilized to control postoperative pain and promote early recovery [75]. Multimodal protocols use combinations of analgesic medications with different mechanisms of action and sites of administration to provide optimal pain relief. Strategies for the management of postoperative pain frequently include the perioperative administration of nonsteroidal anti-inflammatory agents, NMDA inhibitors, steroids, and acetaminophen combined with regional block or wound infiltration with a local anesthetic. Supplemental opioid may be added for breakthrough pain. There is evidence that the preoperative administration of COX-2 inhibitors and gabapentin may be more effective than opioids and other nonsteroidal anti-inflammatory drugs in reducing postoperative pain [76]. Preoperative systemic dexamethasone and perioperative ketorolac and ketamine have also been found to be effective adjuncts to reduce postoperative pain and opioid consumption in a variety of clinical settings [77–79].

Local anesthetics used for peripheral nerve blocks and local infiltration have been shown to reduce postoperative opioid requirements in laparoscopic surgery. Infiltration of a local anesthetic into laparoscopic port sites and other incisions is a common practice shown in the short term to decrease pain scores and the need for supplementary analgesia [80]. A meta-analysis of laparoscopic surgery clinical trials demonstrated that preemptive administration of local anesthetic at the port incision site reduced postoperative pain compared with placebo but was found to have an analgesic effect similar to that of postincisional anesthetic infiltration [81]. Pre-emptive timing of administration was only significant for intraperitoneal infiltration. The analgesic duration of most local anesthetics when administered as a single injection is less than 4–6 hours and may not provide significant long-term postoperative analgesia. Liposomal bupivacaine is a delayed-release local anesthetic approved for injection into the surgical site to produce postsurgical analgesia. Knight et al. found there was no significant difference with respect to opioid consumption and pain control between liposomal bupivacaine and free bupivacaine following injection of incision sites in laparoscopic and robot-assisted urologic surgery cases [82].

The TAP block is a peripheral nerve block that anesthetizes the abdominal wall and is used as part of a multimodal strategy to optimize postoperative pain outcomes. While advocates of the TAP block propose that the analgesia provided reduces postoperative pain, opioid consumption, and related side effects, evidence for TAP block use has been inconsistent. De Oliveira et al. detected a beneficial effect of TAP block on analgesia outcomes after laparoscopic surgery with the preoperative period as the optimal time for administration of the block [83].

A variety of methods have been tested to reduce the incidence and severity of shoulder tip pain. Guido et al. found no difference in shoulder pain after laparoscopic tubal ligation by gasless laparoscopy versus $CO_2$ pneumoperitoneum while Goldberg and Maurer found the compromised surgical exposure and lack of benefits in terms of postoperative discomfort rendered this method unsuitable [84, 85]. Sarli et al. performed laparoscopic cholecystectomy comparing 9 mmHg carbon dioxide pneumoperitoneum with 13 mmHg pneumoperitoneum and noted a decreased incidence and frequency of shoulder tip pain [86]. Sajid et al. concluded that the use of heated humidified $CO_2$ for pneumoperitoneum in laparoscopic procedures is associated with lower postoperative pain and analgesic requirements when compared to dry $CO_2$ [87]. Intraperitoneal local anesthetic nebulization has been found to reduce postoperative pain and referred shoulder pain after laparoscopic cholecystectomy and laparoscopic gynecologic surgery [88–90].

## Postoperative nausea and vomiting

PONV is a common but distressing complication of surgery with a reported incidence of 25–36% [91]. The incidence of PONV has been found to be as high as 79% in certain high-risk populations [92]. It can result in delayed postanesthesia care unit discharge, unplanned hospital admission, and increased healthcare costs. Patient anesthetic- and procedure-related characteristics that confer increased risk for PONV include female gender, history of PONV, nonsmoking status, history of motion sickness, younger age (<50), use of volatile anesthetics and nitrous oxide, duration of anesthesia, postoperative opioids, abdominal procedures, and the laparoscopic approach [91, 93, 94]. While there is no specific guidance for laparoscopic urologic surgery, $CO_2$ insufflation, which causes peritoneal stretching and irritation, is thought to play important role in postoperative PONV [94]. The most recent American Society of Anesthesiologists evidence-based guidelines advocate a comprehensive approach to PONV management. The guidelines include the use of risk scores to ascertain high-risk patients and the implementation of strategies to reduce these risks, such as the use of regional anesthesia and TIVA and minimizing perioperative use of opioids. TIVA with propofol has been shown to reduce the incidence and severity of PONV in patients undergoing RALP [20]. Recommended pharmacologic antiemetic agents for PONV prophylaxis include 5-hydroxytryptamine receptor antagonists, neurokinin-1 receptor antagonists, antihistamines, corticosteroids, butyrophenones, and anticholinergics. Prophylactic antiemetics are recommended only following consideration of patient and procedure risk factors, adverse effects and cost. While 5-hydroxytryptamine receptor antagonists, corticosteroids, and butyrophenones have a documented effect on reducing PONV with similar levels of efficacy, the use of combination therapy utilizing drugs from different classes is preferable. If PONV prophylaxis fails, it is recommended that an antiemetic from a different class than the prophylactic regimen is used [95].

## Complications

### Carbon dioxide embolism

Clinically significant carbon dioxide embolism is a rare but dangerous complication of laparoscopic surgery with a reported incidence of 0.0014–0.6% and an associated mortality rate of 29% [96, 97]. Although a variety of monitoring devices can be utilized to detect gas embolism, transesophageal echocardiography (TEE) is the most sensitive. Kim et al. reported the presence of $CO_2$ embolism in 100% of patients undergoing total laparoscopic hysterectomy with TEE monitoring [98]. Subclinical $CO_2$ embolism was discovered in 17% of patients undergoing laparoscopic radical prostatectomy when TEE was used for detection [99]. Cases of clinically relevant gas embolism have been reported for bariatric, cholecystectomy, radical prostatectomy, hysterectomy, and pediatric laparoscopic procedures [99–103]. The mechanism of embolism is thought to be unintended injection of carbon dioxide into a large vein, artery, or solid organ during initial peritoneal insufflation [104]. Clinical signs of gas embolism depend on the volume of gas and its rate of entry into the circulation and include a sudden drop in end-tidal $CO_2$, hypotension, tachycardia, cardiac arrhythmias, increased central venous pressure, the presence of a "mill-wheel" murmur, cyanosis, and electrocardiogram changes [100]. Immediate treatment requires release of pneumoperitonium, placing the patient in the left lateral decubitus (Durant maneuver), and Trendelenburg position. The patient should be hyperventilated with 100% oxygen to correct hypoxemia and reduce the size of the gas embolus. Volume loading and the Valsalva maneuver elevate central venous pressure and may reduce further gas entry. Vasopressors and inotropic agents are administered as indicated. If these measures are not effective, a multiport central venous catheter may be introduced to aspirate gas from the right atrium or ventricle. If necessary, cardiopulmonary resuscitation should be initiated for persistent hypotension or arrhythmia [105]. Cardiopulmonary bypass and hyperbaric oxygen have both been used successfully to treat symptomatic gas embolism [106, 107]. A prompt collaborative response by the anesthesiologist and surgeon is necessary to limit morbidity when this potentially fatal complication occurs.

### Well-leg compartment syndrome

Well-leg compartment syndrome (WLCS) following surgery in the lithotomy position is a rare complication that requires rapid diagnosis and treatment to prevent serious morbidity and mortality [108]. Reports on the frequency of compartment syndrome in patients who underwent procedures in the lithotomy position range from 1 in 500 to 1 in 3500 [109, 110]. Gluteal and upper extremity compartment syndrome have also been reported following robot-assisted urologic surgery [111]. The pathophysiology involves increased intracompartmental pressure with subsequent decreased tissue perfusion, ischemia of the muscles and nerves, and tissue necrosis [112]. Risk factors include prolonged operative time (>4 hours), patient position (lithotomy and lithotomy-Trendelenburg), obesity, systemic hypotension, muscular lower limbs, type of leg holder, epidural anesthesia, and peripheral vascular disease [109]. Clinical signs and symptoms of WLCS include paresthesia, disproportionate pain in the affected compartment, pain on passive stretch, and tight calves. Supplementary compartmental pressure measurement is recommended when the clinical signs are unclear [113]. Once a diagnosis is made, fasciotomy should be performed urgently to minimize the likelihood of adverse sequelae. Untreated compartment syndrome or delayed fasciotomy can result in limb loss, renal failure, and death [114]. Clinicians must maintain a high level of vigilance in patients with risk factors and explore ways to reduce this risk. Proposed risk-reduction strategies include use of the modified lithotomy position, periodic mobilization of the lower extremities, avoidance of the Trendelenburg position, and ankle dorsiflexion and heel support [115]. Of interest, intermittent compression stockings have been reported to be a risk factor as well as a preventive measure to reduce the risk of WLCS [109, 116].

### Mesenteric ischemia and bowel infarction

There have been several reports of mesenteric ischemia and bowel infarction after routine laparoscopic procedures. Many of these complications occurred in patients with evidence of preoperative cardiovascular, hepatic, or renal compromise. Bandyopadhyay et al. describe a case of large bowel ischemia involving a 78-year-old man who died within 30 hours after an elective laparoscopic transperitoneal inguinal hernioplasty. An autopsy revealed thrombosis of the inferior mesenteric artery and an infrarenal aortic aneurysm with thrombotic plaque on its wall [117]. At least nine cases of small bowel ischemia following laparoscopic cholecystectomy have been reported, many of them fatal [118]. $CO_2$ pneumoperitineum may play a role in this devastating event by reducing mesenteric perfusion in at-risk patients [119]. Techniques that utilize the lowest possible insufflation pressure and intermittent decompression of gas during pneumoperitoneum have been suggested as preventive measures [120]. Intestinal ischemia should be considered whenever nonspecific abdominal symptoms are present after transperitoneal laparoscopic surgery.

## Ocular injuries

Ocular complications of robot-assisted urologic surgery can range from more frequent corneal abrasions to the rare but devastating postoperative visual loss. Corneal abrasions can cause considerable patient pain and discomfort. Possible etiologies include lagophthalmos during general anesthesia resulting in corneal drying, direct mechanical trauma, and chemical injury. Advanced age, general anesthesia, length of surgery, and Trendelenburg positon have been confirmed as perioperative risk factors for corneal abrasions [121]. A retrospective review of 1500 consecutive patients undergoing robotic prostatectomy found corneal abrasions to be the most common anesthesia-related complication, occurring in 3% of cases with the use of eye tape [122]. This incidence was reduced to 1% following the introduction eye patches. In a United States nationwide sample of patients undergoing radical prostatectomy the overall incidence of corneal abrasion was reported as 0.18% [123]. Proposed measures to protect against corneal abrasions include the use of eye patches, and transparent occlusive dressings [122, 124].

Postoperative visual loss (POVL) is a rare complication following robot-assisted laparoscopic surgery. Prolonged operative times in steep Trendelenburg have raised concerns about increased venous congestion in the head, facial edema, and elevated IOP interfering with optic nerve perfusion. Lee et al. reported three cases of POVL from the ASA POVL registry from 2006 to 2011 secondary to posterior ischemic optic neuropathy following RALP [125].

A small randomized trial by Raz et al. found that modifying the Trendelenburg position by placing the head and shoulders horizontally during RALP lowered IOP and accelerated its recovery to the normal range without affecting the procedure [126]. An ophthalmology consult should be considered in patients with history of severe ocular disease and older adults who may have elevated baseline intraocular pressure.

## Peripheral nerve injuries

Nerve injuries related to patient positioning are injuries that occur when a peripheral nerve is subjected to stretching or compression during surgery. Mills et al. reviewed 334 adult urological robot-assisted cases at their institution over a 2 year period and found 22 documented positioning injuries (6.6%). Twenty eight percent of these injuries persisted beyond 6 months. Retroperitoneal lymph node dissection was associated with the highest percentage of patients with injuries (40%), followed by adrenalectomy (17%). Patients at greatest risk for injury were those with a higher ASA classification [127]. Factors associated with positioning nerve injuries can be classified as patient- or procedure-related. Patient-related factors include ASA physical status, body mass index (BMI), variant anatomy, and comorbidities such as diabetes mellitus and vascular disease. Procedural risk factors include patient position and operative duration [127–129]. Lower extremity neuropathies involving the common peroneal, obturator, lateral femoral cutaneous nerve and sciatic nerve from prolonged standard and low lithotomy positioning have been documented with a frequency of 1 in 3608 [130]. Manny et al. reported a lower extremity neuropathy rate of 1.7% in RALP and prostatectomy cases with patients in the low lithotomy position [131]. Koc et al. reported that patients who developed lower extremity neuropathies had a significantly longer operative time than average and that use of a split-leg table was found to put the femoral nerve at risk for injury [132]. Elements of correct lithotomy positioning include the use of boot stirrups, hip flexion of 60–120°, knee flexion of 90–120°, hip adduction of 90° or less, minimal external hip rotation, and the use of specific padding to prevent pressure against the peroneal nerve at the fibular head [133]. Larger BMI is a risk factor for upper extremity injury [128]. Mills et al. reported that 59% of all nerve injuries involved an upper extremity, with the highest proportion of injuries occurring when one upper extremity was adducted while the other was tucked beside the patient. The majority of these injuries occurred in the tucked extremity [127]. Brachial plexus injuries are the most commonly reported peripheral nerve injuries and have been linked to the use of shoulder braces and prolonged steep Trendelenburg positioning [134]. Most guidelines discourage the use of shoulder braces in favor of nonsliding mattresses [133]. Devarajan et al. described three patients who developed brachial plexus injuries with the use of beanbag body supports in steep Trendelenburg position. The authors recommended adduction or tucking of the upper extremities and the use of nonslipping operating table mattresses to prevent cephalad migration of the patient in steep Trendelenburg position [135]. The use of padded arm boards, chest rolls, and elbow padding are also recommended [133]. Documentation of perioperative positioning actions with intermittent assessment of patient positioning is essential.

## Pneumothorax, pneumomediastinum, and pneumopericardium

Pneumothorax (PTX), pneumomediastinum, and pneumopericardium are well-known complications of laparoscopic surgery and can cause significant morbidity. Laparoscopic procedures performed near the diaphragm, inadvertent pleural or diaphragmatic injury, and congenital diaphragmatic defects have been identified as routes for $CO_2$ entry into the mediastinal and pleural spaces [136–138]. PTX has a reported incidence of less than 1% during renal surgery and 3% during adrenalectomy [139, 140]. Risk factors associated with PTX during laparoscopic surgery include prolonged operative times, older age, intraoperative end-tidal $CO_2$ above 50 mmHg, and operator inexperience [140]. Signs of PTX during surgery include hypercapnia, increased airway pressure, hypoxemia, billowing of the diaphragm, and absent breath sounds. Concomitant hemodynamic instability indicates the PTX is likely under tension. While most cases are diagnosed intraoperatively, a valveless Trocar may obscure typical signs of PTX, impeding diagnosis [139]. The authors recommend a chest X-ray in the immediate postoperative period when using a valveless Trocar for procedures close to the diaphragm. Treatment of PTX consists of immediate release of pneumoperitoneum, hyperventilation with 100% oxygen, PEEP, and hemodynamic support.

Severe PTX or cases secondary to underlying lung disease may require immediate simple aspiration or chest tube drainage. Given the favorable absorptive properties of $CO_2$, asymptomatic or hemodynamically stable patients with PTX can be treated conservatively and allowed to resolve spontaneously [141].

## Cardiac patients

Patients with cardiac dysfunction undergoing laparoscopic surgery present a variety of challenges to the anesthesiologist. The physiological effects of $CO_2$ pneumoperitoneum and extreme positioning may be poorly tolerated in these patients. Pneumoperitoneum activates the release of catecholoamines leading to tachycardia, increased afterload, and hypertension. Furthermore, mechanical compression of the aorta by insufflated $CO_2$ may further increase SVR [142]. The tachycardia and increased afterload increase myocardial oxygen demand and the likelihood of ischemia. Further increases in intra-abdominal pressure as insufflation continues decreases venous return, preload, and end-diastolic volume, with the magnitude of decrease in cardiac index directly related to the insufflation pressure [143]. By occupying a less-advantageous position on the Frank–Starling curve, cardiac output can subsequently decrease. Preload augmentation prior to pneumoperitoneum may be necessary. Limiting insufflation pressures should also be considered, as patients with limited cardiac reserve or compensated failure may not tolerate associated hemodynamic changes. Decreased cardiac output leads to decreased oxygen delivery to the periphery with a concomitant decrease in mixed venous oxygen saturation. Patients with severe congestive heart failure and valvular lesions are more likely to develop complications than those suffering from ischemic cardiac disease [144]. The possibility of rising arterial carbon dioxide tension may lead to, or exacerbate, pulmonary hypertension, resulting in right heart strain and ischemia. Standard monitoring may need to be supplemented with invasive monitoring in this patient population. TEE can be used to assess regional wall motion abnormalities, hydration status, and the degree of preload and end-diastolic volume. Invasive arterial monitoring may be useful and pulmonary arterial catheterization may help maximize cardiac output and measure mixed-venous oxygen saturation. Alternatively, noninvasive measures of hemodynamic parameters are commercially available. Noninvasive hemodynamic monitoring provides ease of use while eliminating the risks associated with the placement of invasive monitors. Algorithmic analysis of the Pleth Variability Index (PVI) has been advocated as a method for measuring intraoperative fluid balance, hemodynamic parameters, and hemoglobin. This method utilizes algorithmic analysis of the waveform generated from a standard or modified pulse-oximeter probe. Hemodynamic parameters are derived from respiratory variations in the pulse oximeter waveform amplitudes [145]. While PVI has been shown to reliably predict fluid responsiveness in the mechanically ventilated there are few data to support the use of these monitors in those undergoing laparoscopic procedures [146]. In addition, the impact of abdominal insufflation on the validity of these noninvasive monitors is still unclear. Some data suggest that PVI is falsely elevated with abdominal insufflation. This could assign a false state of hypovolemia and result in the unnecessary, and potentially deleterious, administration of volume expanders [145]. The hemodynamic effects of steep Trendelenburg position commonly used in many robot-assisted urologic procedures appears to be mitigated by the increased intra-abdominal pressures associated with insufflation [142].

## Older patients

Older patients are more susceptible to adverse surgical outcomes because of decreased functional reserve and an increased number of coexisting diseases [147]. Most significantly, changes due to the physiologic stresses of pneumoperitoneum need to be anticipated in this surgical population as the customary insufflation pressures of 10–15 mmHg may cause significant physiologic disturbances. Increased intra-abdominal pressure in octogenarians may decrease the cardiac output by 30% [148]. Heart rate typically increases in an effort to maintain oxygen delivery to the tissues. This compensatory increase may be diminished by medications typically taken by older people, particularly beta-blockers. Elevations in heart rate, SVR, and mean arterial pressure that typically accompany pneumoperitoneum can increase myocardial workload and the risk of ischemia. The presence of atrial fibrillation further decreases cardiac reserve due to loss of the atrial contribution to ventricular filling.

The pharmacokinetics and pharmacodynamics of drugs are significantly altered in older people. Elderly patients tend to have increased adipose tissue, decreased muscle mass, and decreased total body water accounting for many of the pharmacokinetic changes [149]. The subsequent decreased volume of distribution can lead to exaggerated hemodynamic responses to induction agents and other drugs. Older people, particularly the malnourished, have a lower serum albumin concentration resulting in considerably higher plasma concentrations of unbound drug. Drug doses should be lowered and titrated to effect in these patients to avoid relative overdose. While is important to recognize age-related physiologic changes, age alone has not been associated with an increased risk of intraoperative or postoperative complications [150]. Laparoscopic renal and adrenal surgery, radical prostatectomy, and robot-assisted radical cystectomy in older adults have all been shown to be well tolerated with low perioperative morbidity.

## Pregnancy

Pregnancy-induced anatomical and physiological changes must be understood to provide optimal care to these surgical patients. Approximately 1–2% of pregnant patients require a non-obstetric surgical intervention during their pregnancy, representing approximately 80 000 cases per year [151]. Laparoscopic partial nephrectomy for renal cell carcinoma in the pregnant patient has been described in the literature [152]. While there are numerous case reports that support the use of laparoscopy during pregnancy, by the end of the second trimester the size of the uterus often interferes with the laparoscopic approach and open surgery may be indicated [153]. Additionally, many laparoscopic-specific maternal and fetal complications bear consideration, including uterine and/or fetal trauma, fetal acidosis from carbon dioxide absorption, decreased maternal cardiac output, and decreased uteroplacental blood flow secondary to increased intraperitoneal pressure [151]. Pneumoperitoneum can initiate premature labor. Preservation of maternal hemodynamics, uteroplacental blood flow and avoidance of maternal and fetal hypoxia is paramount. While the retroperitoneal approach to the kidney for laparoscopic nephrectomy has been described, the best approach remains controversial. The transperitoneal approach affords the surgeon a larger working space while the retroperitoneal approach provides for early control of the renal vasculature and minimizes bowel and uterine manipulation, thereby potentially decreasing the risk of premature labor [154]. The Society of American Gastrointestinal Endoscopic Surgeons (SAGES) has issued guidelines for laparoscopic surgery during pregnancy that include deferring surgery until the second trimester and maintaining low pneumoperitoneum pressures (<15 mmHg) [155]. Close interdisciplinary communication and cooperation is essential in the provision of perioperative care of these high-risk patients. The mother should be fully informed of the low risks of teratogenicity of most anesthetic agents, and of the significant risk of preterm labor.

## Obesity

Many of the complexities of caring for the obese surgical patient have been well described. Careful attention to the comorbidities unique to the obese aids in their safe management. These comorbidities include pulmonary, airway, and cardiac changes, among other concerns. Morbidly obese patients have a higher potential for difficult mask ventilation, laryngoscopy, and intubation. The obese patient's large tongue, redundant oropharyngeal tissue, atlantoaxial joint limitation, and presternal fat deposits inhibit movement of the laryngoscope and increase the difficulty of direct laryngoscopy. Factors such as Mallampati classification and neck circumference are predictive of a difficult airway [156].

Chest wall compliance is decreased in the obese due to increased adipose load on the chest and abdomen. Lung compliance is decreased secondary to increased pulmonary blood volume and is proportionate to the degree of obesity. Expiratory reserve volume is decreased and may be exceeded by the closing volume, leading to air entrapment. Pneumoperitoneum may exacerbate these changes. Surprisingly, the decrease in lung compliance upon insufflation in normal weight patients has been shown to be equal to or even greater than the decrease seen in morbidly obese patients [157]. Morbid obesity is associated with sleep apnea, elevated pulmonary pressures, and right ventricular hypertrophy and failure. Pre-existing pulmonary hypertension may be aggravated by insufflation induced hypercarbia. Thorough preoperative assessment and optimization and continued postoperative monitoring of respiratory parameters is essential in patients with these comorbid conditions. Positioning of the obese patient for laparoscopic surgery can be challenging, as these patients are at greater risk for nerve injury. The most frequently reported complication is ulnar neuropathy and careful attention to and padding of stress points is imperative [158].

BMI is associated with major complications following laparoscopic surgery for renal cancer with risk increasing by 14% for every unit increase [159]. Once again, the use of noninvasive monitoring techniques may aid in the management of these patients. The limitations of PVI, however, may be pronounced in obese patients.

# Laparoscopy Surgery: Basic Instrumentation

*Ornob Roy*

*Carolinas Medical Center, Charlotte, NC, USA*

## Introduction

Even in the face of significant advances in robotic and endoscopic surgery, laparoscopy remains the method of choice for multiple urologic procedures and advances continue to be made in instrumentation. Significant technological improvements have been made over the last decade to ameliorate problems, including limitations of previous generations of optics, maintenance of pneumoperitoneum, intracorporeal retractors, and hemostasis. Well-established instruments such as graspers, clip appliers, intracorporeal bags, and fascial closure devices have remained largely constant with few adjustments.

Advanced laparoscopy, much like robotics and endoscopic surgery, is only limited by instrumentation, both in availability and applicability. Therefore, it is the author's firm belief that extensive knowledge of laparoscopic instrumentation is necessary to continue to offer the best surgical care for our patients.

## Access

### Transperitoneal

Laparoscopic instrumentation has not changed much since the introduction of the Veress needle in 1947 [1]. The Veress remains widely used as a safe and efficient access to the peritoneal cavity while causing minimal trauma [2]. It is a 2 mm needle with a spring-loaded blunt obturator that is hidden during penetration of firm structures, such as fascia or skin (Figure 80.1). The blunt obturator deploys beyond the beveled edge of the needle when encountering softer, mobile structures such as bowel or intraperitoneal organs. Although a blind access technique, several tests such as aspiration, monitoring of insufflation pressure, and the "saline drop" tests can be used in combination to confirm entry into the peritoneal cavity [3] (Video 80.1).

For those uncomfortable with blind access or for patients with extensive previous abdominal surgery, the Hasson technique, open entry through a small incision with direct visual entry, provides a nearly failsafe alternative. Special blunt-tipped camera Trocars are manually deployed upon confirmation of entry for camera placement and insufflation. These Trocars will be described in subsequent sections [1].

### Retroperitoneal

The retroperitoneal space is only a potential space, making it ineffective for access and initial insufflation with a Veress technique. Access can be achieved by the Hasson technique with the use of a balloon dilator under laparoscopic vision. Although older reports describe filling a surgical glove or condom with air or saline once the proper space is entered, modern dilating balloons allow for manually controlled dilation with air while still maintaining visualization with a laparoscope [4]. Balloons are typically either spherical or oval in shape (Figure 80.2). Once the potential space is created correctly, the balloon port is switched to a traditional Hasson port to prevent loss of insufflation and dislodging.

## Insufflation

Carbon dioxide insufflator technology has remained unchanged for several years. The regulator box limits the inflow of the gas to the surgeon's preference, with auto-adjustment based on desired cavity pressures, while constantly displaying actual cavity pressure (Figure 80.3).

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

Companion website: www.wiley.com/go/smith/textbookofendourology

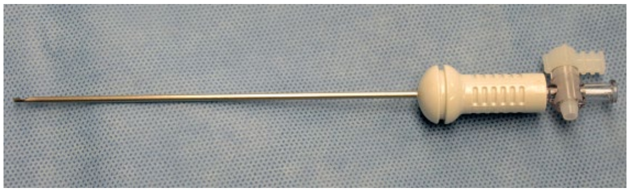

**Figure 80.1** The Veress needle is used for blind percutaneous access to the peritoneal cavity.

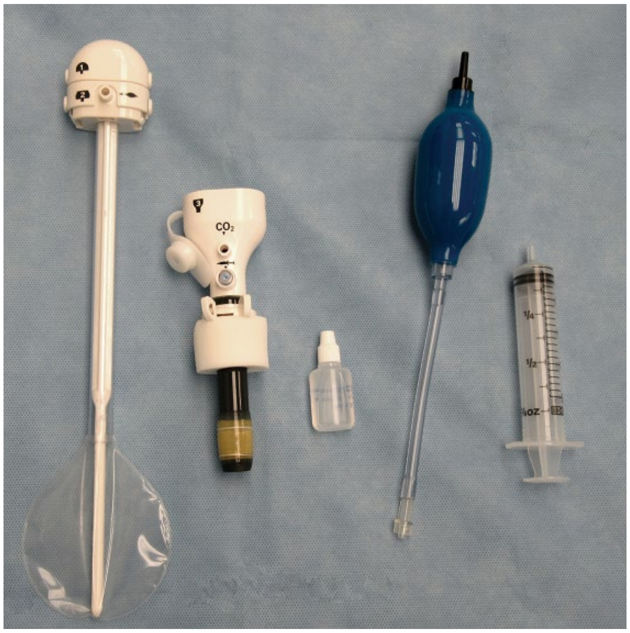

**Figure 80.2** Retroperitoneal access balloon set is used to expand the potential space of the retroperitoneal cavity.

Although initially described for patients with chronic obstructive pulmonary disease (COPD), helium gas is seldom used due to poor availability and very little practical need [5,6]. It is the author's experience that even patients with severe COPD can undergo laparoscopic surgery with $CO_2$ insufflation, with necessary adjustments to lower pressure or the volume and/or frequency of the ventilator.

One advance in insufflation is the advent of the AirSeal® system (SurgiQuest, Milford, CT, USA), which uses recirculated $CO_2$ to allow for a valveless Trocar while simultaneously providing insufflation and preventing loss of pneumoperitoneum. Without valves, this Trocar does not cause "smudging" with camera insertion and has no impedance to transfer of needles, hemostatics, bags, and specimens to and from the peritoneal or retroperitoneal cavity. This system also provides excellent smoke evacuation and can be switched to "conventional" insufflation if desired.

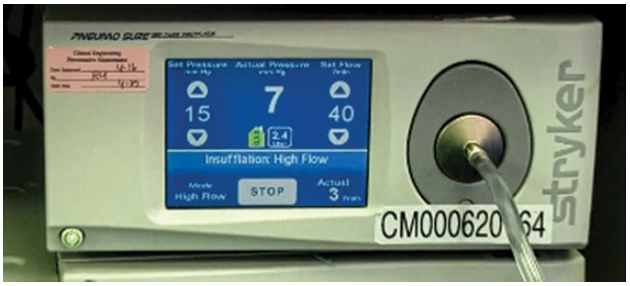

**Figure 80.3** An insufflator is used to deliver inert gas and regulate intraperitoneal pressure throughout the operation.

## Trocars

### Hasson

Usually used for the camera Trocar, Hasson Trocars are deployed into the access site created by the Hasson technique. They come in either a wedge/plug configuration or with a small-volume intracorporeal anchoring balloon. These additions to the simple cylindrical Trocar are essential for open or Hasson port placement to prevent constant loss of pneumoperitoneum and dislodgement of the port, as the size of the fascial incision is larger than with a puncture technique. To prevent loss of pneumoperitoneum during instrument exchange, these Trocars have an internal rubber diaphragm.

### Visual entry

Visual entry Trocars are cylindrical in shape and generally have a clear sheath and obturator with a dilating cone tip. The obturator is unique in that it will allow a 10 or 5 mm laparoscope lens to fit inside and visualize entry through the layers of the abdomen (Figure 80.4). The Trocars' anti-slip mechanism is such that since no fascial incision is made upon placement shear forces are stronger and there are small ridges on the surface of the outer sheath to hold it in place. To prevent loss of pneumoperitoneum during instrument exchange, these Trocars have an internal rubber diaphragm.

### Reusable

Aesculap (Center Valley, CA, USA) offers a set of reusable, metal Trocars ranging from 3.5 to 12 mm in size (Figure 80.5). A series of reusable nipples and a mechanical internal one-way valve prevent loss of pneumoperitoneum during instrument exchange. These Trocars are deployed using a screw-technique, employing a threaded screw around the outside of the Trocar that both dilates and anchors the Trocar during surgery.

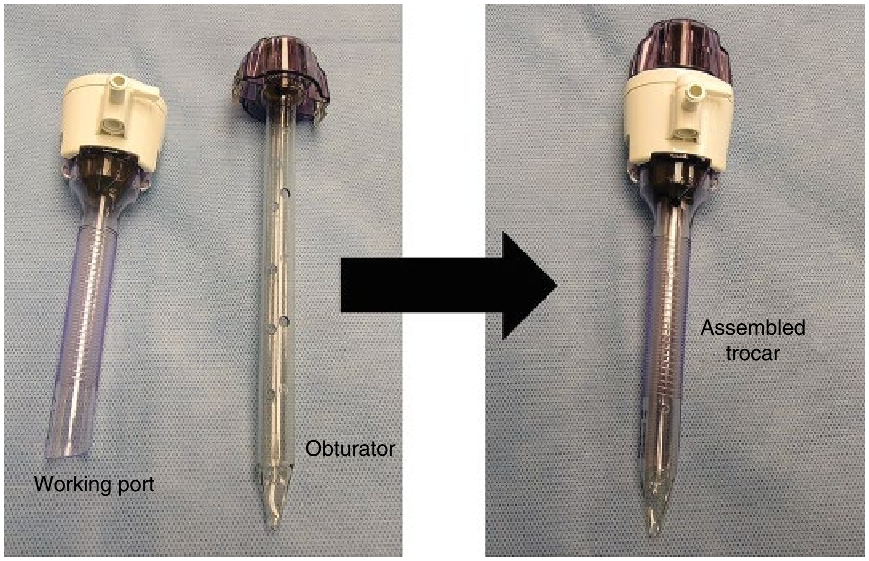

**Figure 80.4** Visual entry Trocar is used with a zero-degree lens laparoscope placed within the clear obturator to visualize penetration of the layers of the abdominal wall. Right: the assembled obturator-Trocar device.

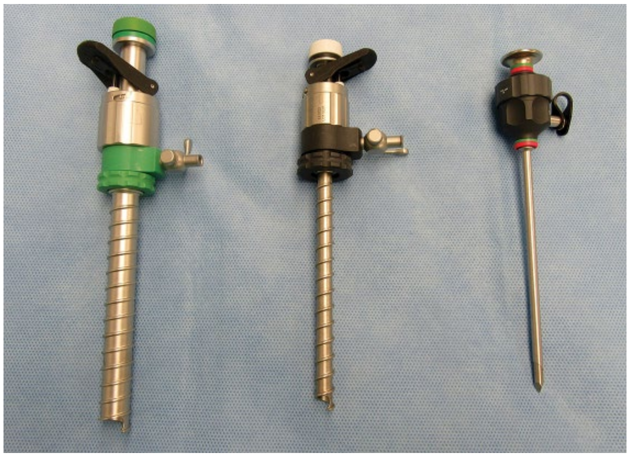

**Figure 80.5** Reusable Trocars can be deployed using blind or visual entry, utilizing a screwing motion with gentle downward pressure for precise Trocar placement.

### Internal dilating

The Step™ system (Medtronic, Minneapolis, MN, USA) is a radially dilating system of bladeless Trocars that are initially deployed by Veress needle. The Trocars dilate to full working size by placement of an internal dilator which opens the expandable Trocar sheath. This offers the advantage of minimal trauma to the abdominal wall and the small Trocars can be expanded to a larger diameter intraoperatively without the need to remove and replace [7]. Radially dilating Trocars have the smallest defect size when compared to single and triangular cutting bladed Trocars, but required the greatest insertion force [8].

Of note, there are a variety of other Trocars that have been developed and used for single-port and robotic surgery that will not be discussed in this chapter.

## Vision

Perhaps the greatest advances in laparoscopic surgery have been in intracorporeal visualization. Advances in resolution, magnification, three-dimensional (3D) optics, digital image processing, and advanced image enhancement has hastened the widespread adoption of laparoendoscopic surgery for even more complex procedures.

Currently, all laparoscopic optics require a reusable camera and lens system that can be sterilized and connected by cables to an image-processing set-top box. The laparoscopic tower holds one or multiple set-top boxes that are not sterilized and can digitally enhance and transmit the image to a monitor in the operating room (OR). The tower also houses the light source, a high-intensity bulb transmitting light to the laparoscope via a sterile cable (Figure 80.6).

### Rigid endoscopes

Rigid endoscopes are the traditional lenses used to transmit light from the intracorporeal cavity to an image-processing camera. They incorporate a separate fiber-optic channel to transmit light into the body along the outer edges of the lens. Currently, these lenses offer different degrees of angulation (0–45°) and increasing size, from 2.7 mm “needlescopes” to standard 10 mm lenses for laparoscopic procedures. Generally, increasing the angle and decreasing the overall diameter diminishes image quality. On average, rigid endoscopes provide a 70° visual field. These lenses require a separate “camera” and light-source cable attached to the extracorporeal laparoscopic tower to provide image transfer and light.

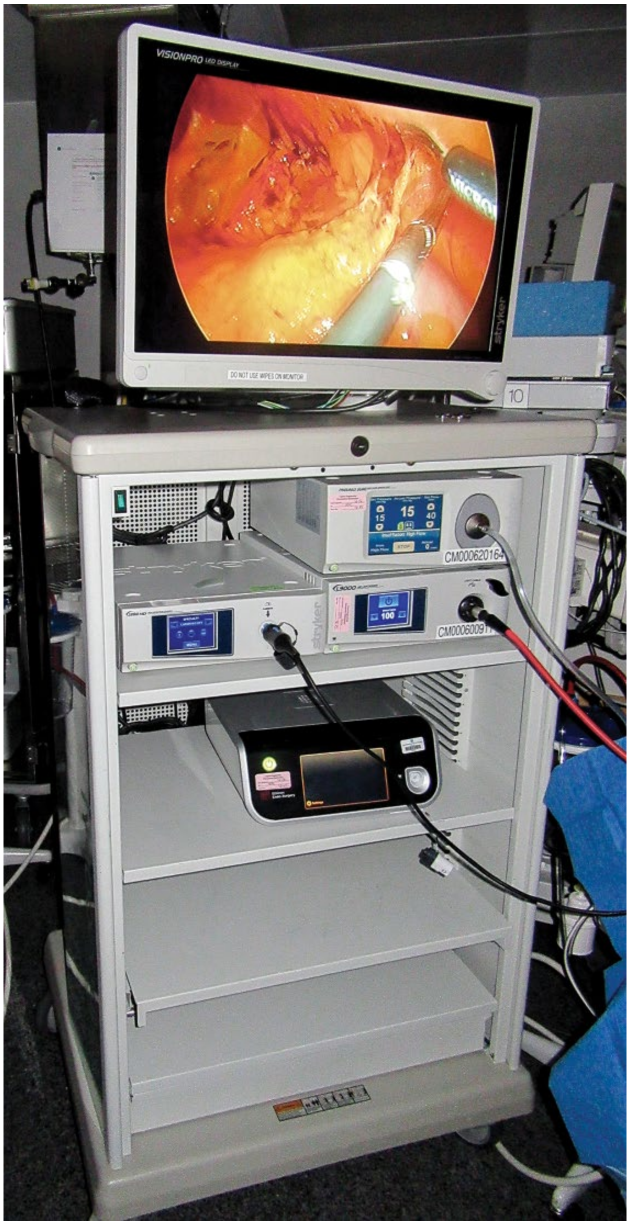

Figure 80.6 Laparoscopic set-top box tower with LCD display monitor, insufflation device, image-processing hardware, and light source.

### Flexible endoscopes

The Endoeye Flex 3D® (Olympus, Center Valley, PA, USA) is a 5 mm rigid-shaft digital endoscope with an articulating tip containing the camera and lens. This provides a high-definition (HD) image and angulation from 0 to 100°. Visual field is 85°. As with the other lenses, flexible endoscopes are sterilized using a standard autoclave. A single cord extends from the extracorporeal handle to the image-processing and light-supply tower.

## Light source

Halogen, xenon, and light-emitting diode (LED) are the most commonly used light sources. Aside from the LED, halogen and xenon can generate significant thermal energy when in contact with intraperitoneal contents. Currently, light sources are housed in an image-processing tower and transmit light using sterile fiber-optic cables [9].

## Image processing

Most image-processing occurs on the set-top box in the tower mentioned above. Processing can and usually does involve adjustments of brightness (automatic or manual), hue, contrast, and display size. Many vendors offer predetermined or memorized settings optimized to operation type or surgeon preference.

### Near-infrared technology

This technology requires injection of a fluorophore (commonly indocyanine green or ICG) that preferentially deposits in vascular tissues. A variety of different light sources can be used to excite the fluorophore and cause it to emit light. This light is then preferentially detected using one of several optical filters, highlighting the desired target tissues. In urology, the most common use for near-infrared technology is in identifying renal tumors and ureters.

### Narrow-band imaging

Narrow-band imaging uses wavelengths specific for limited green and blue visible light to highlight vasculature of mucosal surfaces. Although primarily used in endoscopic procedures, many image-processing platforms used in laparoscopy incorporate this technology.

### Three-dimensional imaging

3D imaging was popularized in surgery primarily by the da Vinci® surgical system. The da Vinci® system utilizes a binocular lens and camera that projects through two separate eyepieces into a surgeon console. This concept has been applied to laparoscopic surgery through binocular surgeon headsets. While studies have shown that the 3D systems improve surgeon performance, they have not been widely accepted or utilized due to reports of dizziness, operator discomfort, technological complexity, and high cost [10–12]. For laparoscopic surgery, single screen-suspended or set-top monitors have been used to display 3D images (see Display). Early versions of 3D imaging were limited to standard definition (SD), but newer products offer HD quality of 3D images.

### 4 K

Ultra-HD or 4 K imaging provides approximately four times the number of pixels over the same area as an HD image (4 K is 3840 × 2160; HD is 1920 × 1080). This increased resolution is best appreciated at close viewing distances and is highly applicable to laparoscopic surgery. Current limitations only include cost and availability, as displays and image-processing technology are already mature in nonmedical applications [13]. Although few ORs currently employ this technology, 4 K will certainly offer improved visualization in laparoscopic surgery.

### Ultrasound

A variety of vendors offer handheld ultrasound probes designed to fit through a 10–12 mm port. These are articulating and can offer Doppler overlay. BK Ultrasound and Hitachi Aloka Medical are widely available and can double for use in robotic surgery. This technology is essential for partial nephrectomy and can also be used to identify vessels hidden by scar tissue.

## Display

Monitors, either suspended from the ceiling with a boom or on a set-top box tower, are the standard choice for image display in the OR. An OR usually requires at least two monitors so that everyone in the OR can observe the operation and share the display, depending on the placement in the OR. In the United States, it is now commonplace to find HD monitors in the OR. In addition to being able to display high-resolution images, these monitors provide improved contrast and resolution to SD images.

Newer monitors can be integrated with 3D technology to provide 3D display to surgeons and others in the OR without the need for 3D glasses. There are several vendors through which these medical systems can be purchased.

## Extracorporeal assist devices

### Table-mounted instrument holders

Available from several vendors, table-mounted instrument holders are designed to take the place of a human bedside assistant by keeping secondary retracting instruments from moving during laparoscopic surgery. These often have either articulating or flexible locking arms that attach to the rails on the operating table. They are generally low in profile and can be mounted to allow the surgeon to operate unencumbered. The author has considerable experience with such devices from Thompson Surgical Instruments (Traverse City, MI, USA) that have performed reliably, but many different vendors offer table-mounted instrument holders.

## Graspers

Such a wide variety of laparoscopic graspers exists that here are recommended general categories that are felt to be essential to common laparoscopic procedures. In general, most are available in locking or nonlocking forms and rigid or rotatable forms. The author favors locking and rotatable instruments due to their versatility, but these instruments tend to be more fragile and sometimes more cumbersome and optional for straightforward procedures. Nearly every type of end-effector available in open surgery can be found in laparoscopic instrumentation.

### Bowel grasper

Bowel graspers have a long, single-hinged effector with small or large-gapped ridges to prevent slippage of tissue. Grip strength is purposefully weak to prevent crush injury. These are not meant for grasping needles or tissues with high turgor.

### Dissecting graspers

Dissecting graspers generally have a shorter end-effector, are single-hinged, and can be straight-tipped or carry varying degrees of curvature. They can range from a sharply tapered “dolphin-nose” effector to a broad tip. These tend to be the workhorse or most versatile instruments during surgery and have moderate grip strength. The author recommends having several different sizes and shapes of tips available for each case (i.e. curved versus right-angle versus straight tips).

### Needle-holders

Needle-holder graspers have short, single-hinged end-effectors with tremendous grip strength ideal for holding needles. They can be locking or nonlocking and sometimes “self-righting,” with a single matched pair of grooves in the end-effector to force the needle into a 90° position. These should not be used to grasp tissue due to the potential for crush injury.

## Clamps

Many standard graspers can serve as a “weak” clamp but do not resist tissue slippage very well. For this reason, various locking clamps are available. Small intracorporeal, spring-loaded “bulldog” clamps can be placed without losing the use of a port to keep them in place. Special handheld instruments passed through ports are used to deploy and remove these clamps. In addition, large “Satinsky”-style locking clamps with long handles can be used to clamp the renal hilum or major vascular injuries to the inferior vena cava. Of note these larger Satinsky-style clamps may require a flexible Trocar for deployment.

## Retractors

Although traditional locking graspers can be employed as retractors when clamped onto the body wall intracorporeally, several devices also exist for this purpose.

### Transabdominal stationary

These retractors are primarily designed to retract the liver or spleen and can be fixed-hook (e.g. Nathanson Hook®, Aesculap) or triangular self-forming (e.g. Lapro-Flex®, Mediflex Surgical Products, Islandia, NY, USA) in shape. The handle remains extracorporeal and can be held by a surgical assistant or, more often, by a table-mounted instrument holder.

### Transabdominal mobile

Held by a surgical bedside assistant, a “fan” retractor employs a collapsible set of long blades with blunt tips expanded to a triangle shape to retract large surface areas. This is available in disposable or reusable forms and comes in 5 and 10–12 mm sizes.

In disposable form, the Endo-Paddle™ (Medtronic) employs a collapsible, rectangular frame covered by a fabric mesh without fenestration. This is in only available in 12 mm size and is very useful for intestinal retraction due to the lack of fenestrations.

## Cutting

### Scissors

There have been no significant advances in laparoscopic scissors over the last 10 years, aside from the development of disposable blades. Blades can be either curved, which is more common and versatile, or straight with a fine tip, such as Potts scissors. Curved-tip scissors are available both with and without the ability to apply monopolar cautery. If used with cautery, the gentle curve can also be used for fine dissection much in the same way as a hook cautery device (also available in laparoscopic form). Curved scissors can be found most commonly in a 5 mm variety or in a heavy-duty 10 mm variety for heminephrectomy. The advent of disposable scissors allows consistently sharp blades best for fine dissection and delicate tissues. The entire instrument or just the tip can be single use. Microline Surgical (Beverly, MA, USA) and other vendors have such a line of “reposable” instruments, with single-use tips and a reusable handle and shaft.

## Hemostasis

Along with improvements in optics, advances in hemostatic technology for laparoscopic surgery have provided the significant benefit to surgeons over the last decade. Both energy-based instruments and biologic agents have seen a proliferation of options available during laparoscopic surgery and more are in development. There are so many options available at the current stage, with no single-proven single superior product, that surgeon preference after trying various competing products should drive choice.

### Energy-based devices

**Monopolar**

The oldest form of energy-based hemostasis employs the use of monopolar current. Common instruments that use monopolar current include shears and small dissecting hooks. In monopolar current, energy is dispersed from the active electrode to a larger return electrode, transferring heat from a single probe to vascular tissue and causing desiccation and coagulation. Injuries to surrounding tissues are common in monopolar cautery due the risk of capacitive coupling or breaks in the insulating coating; however, the advent of active electrode monitoring (AEM) has decreased the risk for injury [14,15]. This form of hemostasis remains useful in laparoscopy for its ease, precision, and speed.

**Argon beam**

The argon beam coagulator (ABC; Conmed, Utica, NY, USA) uses the inert gas argon to deliver monopolar electricity safely for hemostasis. In the ABC, a directed beam of argon gas ionizes to aid in the conduction of radiofrequency electric current. This is most useful for control of solid-organ surface bleeding on the liver, spleen, or kidney. It is important to vent the peritoneum during use to prevent buildup of pressure and gas embolism, the most serious danger of using an ABC [15]. In addition to the risks mentioned above, this method has become been utilized less due to the cumbersome equipment, the need for venting, and the improvement of deployable hemostatics.

#### Bipolar

Most newer energy devices use bipolar current, or the transfer of energy between two prongs of an instrument to contain heat transfer to the area between the prongs. This energy type is especially useful for ligation of small vessels (<8 mm) due to the utilization of simultaneous compression with coagulation and desiccation. The simplest bipolar device is a small grasping forceps that transfers a small amount of current between its two jaws. Newer devices with several vendors are more complex, offering impedance detection to verify when a vessel is truly “sealed,” an integrated cutting blade to combine sealing with division, and technologies to limit the spread of energy to surrounding tissues. Bipolar electrosurgery requires lower voltages than monopolar electrosurgery, resulting in a decrease in potential injury. These devices are very useful in laparoscopic surgery and have been shown to reduce blood loss, operative time, and the use of clips and ties intracorporeally [16,17]. Bipolar instruments range in diameter from 3 to 10 mm and come in a variety of tip shapes. Thermal spread of energy of devices ranges from 2 to 4 mm [18]. Some of the more advanced and widely used models are the Ligasure™ (Medtronic), Enseal® (Ethicon Endo-Surgery, Cincinnati, OH, USA), Caiman® (Aesculap), and PKS™ OMNI (Olympus) (Table 80.1).

#### Ultrasonic

Ultrasound technology can also be used for precise cutting and coagulation by converting electrical energy into vibration. The vibrations induce protein denaturation by causing internal cellular friction and breaking down hydrogen bonds [16]. The Harmonic Synergy® scalpel (Ethicon Endo-Surgery) utilizes pure ultrasonic energy through a vibrating cutting blade (55 kHz) to efficiently heat, compress, seal, and divide tissue and vessels that are less than 7 mm. The cutting blade does generate heat and should not be adjacent to delicate tissues not intended to receive high temperatures. Thermal spread is reported to be between 1.7 and 2.2 mm.

### Hemostatic agents

The development of deployable agents adds a useful tool to laparoscopic surgery. These agents have been in some form of development or use since the early twentieth century, but were initially fraught with problems and concerns of carrying viral or bacterial organisms. In modern times, improved sterilization techniques have negated this concern. In addition, allergic reactions are increasingly rare due to improved technology and decreased use of bone wax [19]. Many different vendors offer such agents, but over the last decade the categories of general types of agents have not changed. In general, there five categories: fibrin sealants, gelatin-based products, oxidized cellulose, collagen products, and microporous polysaccharide hemospheres [20,21] (Table 80.2). Different formulations of these products can be deployed by direct placement

**Table 80.1** The four most commonly used bipolar sealing devices are available within 5 and 10 mm shaft size, with opposing jaws for compression and delivery of energy. They all have the ability to sense tissue properties to confirm the seal and must be connected via cord to a nonsterile set-top box [16–18].

| | **Ligasure™** | **Enseal®** | **Caiman®** | **PKS™ OMNI** |
|---|---|---|---|---|
| Manufacturer | Medtronic | Ethicon | Aesculap | Olympus |
| Max vessel size | 7 mm | 7 mm | 7 mm | 7 mm |
| Mechanism | Delivers high current, low voltage along with pressure from the jaws to tissue and uses the body’s own collagen and elastin to create a permanent fusion zone | Delivers high uniform compression throughout the device tip and offset bipolar electrode design helps contain energy flow and concentrate energy on tissue and within the jaws | Pulse waveform modulation (PWM) monitors and delivers current in relation to power, voltage, and resistance | Plasma kinetic technology delivers a high current and very low voltage to the tissue while a series of rapid pulses allows a cooling phase during coagulation to decrease lateral thermal spread |
| Lateral spread [23,24] | 2–3 mm | <1 mm | <1 mm | 2–6 mm |
| Features | Fast sealing time (10 seconds)<br>Highest burst pressure (385 mmHg) | Offset electrode design reduces lateral thermal spread | Less operative time due to larger jaw<br>Tips close first to prevent slippage and provide uniform compression | Fast sealing time (11.1 seconds) |

**Table 80.2** Commonly used and widely available hemostatic agents can all be deployed laparoscopically on to bleeding tissues. Each agent has potentially different advantages depending on tissue type and situation, but selection is primarily surgeon-dependent [19–21].

with forceps, spray, or even drip application. Prices of these agents may vary considerably with sometimes unclear differences in advantages for different purposes.

## Stapling

Multiple vendors offer reliable stapling devices to ligate and divide larger structures, ranging from large blood vessels >5 mm to intestines and even hepatic or adrenal tissues. Although powered options are available, most devices are manual, meaning the compression force is initiated manually and applied to the tissue being ligated immediately prior to deployment of the staples. It is important to note that there are different varieties of "load," or staple size and arrangement, that are optimized to certain tissues. Most commonly, vascular staples are small and closely situated in multiple rows while intestinal staples are larger with longer teeth to span the width of the intestinal wall. Staplers generally require a 12 mm port for use. The most useful stapling devices are able to rotate 180° or more along the shaft axis and articulate to >60°.

## Clips

Laparoscopic clip appliers come in two varieties, auto-reloading and manually reloading. Appliers range in size from 5 to 12 mm. The auto-reloading variety generally will carry 12–15 metal clips that are deployed by a variable squeezing mechanism in the handle. Once the clips are finished, another device must be opened to deploy more clips. In some cases, the clips can be removed by sliding them off gently, but this is not always possible.

Manually loaded clips are often plastic with a locking "clasp" that can also be removed using a different removal tool. An example is the Weck® Hem-o-lock® clips (Teleflex Medical, Research Triangle Park, NC, USA) that can ligate up to 16 mm structures. These clips are loaded individually at the bedside bench, generally by a scrub technologist, and handed to the surgeon for deployment intracorporeally.

## Suction-irrigation

These devices are essential for laparoscopy, except in cases of hand assistance. The primary purpose is to clear the area of dissection from blood or other spilled fluids to allow proper visualization. There are a limited number of widely used combination suction-irrigation devices. The two most widely used disposable devices are made by Bard Medical (Covington, GA, USA) and Stryker Corporation (Kalamazoo, MI, USA), but many acceptable alternatives exist. In addition, reusable metal instruments are also available. They are connected via sterile suction tubing to a battery-powered pump mechanism, saline bag, and reservoir near the operating table outside of the sterile field.

## Suturing instruments

Suturing during laparoscopy can be challenging due to decreased degrees of freedom, restricted space between instruments, and limited instrument access points due to port placement [22]. A variety of laparoscopic needle drivers are available. All available drivers have an end-effector needle-holding (short-nosed) forceps with high grip strength. Locking and nonlocking varieties exist. Some end-effectors have a slight curved tip that may be useful in small suturing spaces. Self-righting needle drivers with a shallow groove in the end-effector may be helpful because adjusting the needle angle on the driver laparoscopically can be cumbersome or challenging. The authors encourage laparoscopic surgeons to try both locking and non-locking varieties and multiple different handle types (such as a pistol, ringed, or straight grip) before committing to a certain driver.

An auto-suturing device (e.g. Endo Stitch™ by Medtronic) is also available that is very fast and easy to use for simple intracorporeal suturing. This device passes a small two-sided needle attached to a suture back and forth between two prongs on the end-effector. There are 5 and 10 mm devices available with a variety of suture sizes and types. Disadvantages of these devices include the inability to "back" a needle out to make a slight adjustment and difficulty navigating a complex curve or thick tissue due to the small, straight double-pronged end-effector.

## Entrapment bags

Entrapment bags are critical to oncology cases and useful in many other cases to avoid spillage and assist with extraction. These can be reusable, disposable, or even completely deployed off the laparoscopic device (e.g. LapSac® by Cook Urological, Spencer, IN, USA). Sizes of the bag vary considerably and all are made of impermeable materials atraumatic to the abdominal wall during extraction. Necessary port sizes to deploy the bags commonly range from 5 to 15 mm (Figure 80.7).

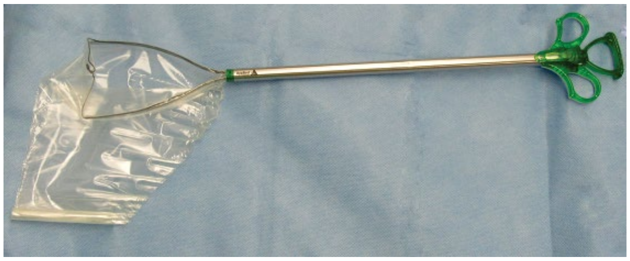

**Figure 80.7** Single-use entrapment bag, inserted into the abdomen through a 10–12 mm port while collapsed within the shaft and opened intracorporeally under laparoscopic vision. Once the specimen is within the bag, a drawstring is pulled to tighten the outlet to prevent spillage.

## Hand-assist ports

In intraperitoneal laparoscopic surgery, utilizing one hand intracorporeally can be a useful transition from a traditional open surgeon to laparoscopy. In addition, advanced laparoscopic surgeons may choose to utilize "hand-assistance" for complex operations. Although not necessary, multiple ports exist that can accommodate a hand while maintaining pneumoperitoneum and allowing quick and repetitive passage of the hand in and out of the abdomen. These ports span the entire abdominal wall with an anchoring ring inside the peritoneal lining and an outer anchoring ring on the skin surface. A popular choice is the GelPort® system (Applied Medical, Rancho Santa Margarita, CA, USA), which has a self-sealing gelatin-like matrix that can be cut to allow traditional laparoscopic ports in addition to a hand. Other ports may allow for adjustment of the circumferential pressure around the wrist and forearm based on surgeon preference.

## Closure devices

Because such small incisions are utilized to place laparoscopic ports (3–12 mm), closing the fascia may be cumbersome, especially in obese patients. Laparoscopic suture-passing devices have been developed to assist with fascial closure. These are 2 mm puncturing needles with a tip that can securely grasp and release the suture. The suture is passed through the abdominal wall, usually subcutaneously, and then regrasped intracorporeally under laparoscopic vision through a separate puncture on the opposite side of the incision to be brought out and tied extracorporeally. Devices range from a simple straight 2 mm grasping needle to a combination of needle and cone-shaped guides to produce more consistent throws and a predictably reliable closure (e.g. Carter-Thomason CloseSure System®; Cooper Surgical, Trumbull, CT, USA). This technique is nearly essential in the morbidly obese and can significantly decrease fascial closure time while also ensuring adequate closure.

## Other instruments

As more emphasis is placed on a quicker recovery and less time to return to normal activities after surgery, the footprint of laparoscopic surgery in urology is expanding to cases never before utilized, such as for urinary diversion and inferior vena cava thrombectomy. For this reason, and with the advancement of derivatives of laparoscopic surgery, namely single-site, natural orifice, and robotic surgery, new instruments are perpetually in development and are not all mentioned here.

## The da Vinci® System

The da Vinci Surgical System (Intuitive Surgical Inc., Sunnyvale, CA, USA) consists of three core components: a surgeon console, a vision tower, and a patient cart with four robotic arms (Figure 81.1). One arm controls the camera and the remaining arms manipulate surgical instruments. On the da Vinci Xi Surgical System the camera can be placed on any of the four robotic arms, allowing for port hopping during a procedure. The instruments have seven degrees of freedom, including external pitch, external yaw, insertion, grip, roll, internal pitch, and internal yaw, allowing for wristed, articulated movement. The surgeon sits at the console and is presented with a high-resolution three-dimensional view of the surgical field.

### Surgeon console

The console includes a stereo viewer with sensors as a safety mechanism. If the surgeon's head is not positioned in the console, the system will be deactivated and the robotic arms will be locked in place. By using the two master controllers, the surgeon's hand movements are processed by a computer and sent to the patient cart, which controls the robotic instruments inside the patient's body in real time. Motion scaling can be performed to filter out physiologic tremor, allowing for finer movements [1]. Computer processing also facilitates intuitive motion, whereby movement of the surgeon's hands is translated to the movement of instruments. This differs from laparoscopic surgery, in which, to move the instrument tips left, right, up, or down, the surgeon must actually move his or her hand in the opposite direction.

Adjustments to the system, such as camera control, scope setup, audio volume, and console ergonomics, can be made while the surgeon is seated at the console. The console surgeon can also toggle between robotic arms. These tasks can be accomplished using the console's hand and foot pedal controls. The console is connected to the vision cart and patient cart components via cables.

### Optical system

The da Vinci system offers three-dimensional magnified vision. On the da Vinci Si Surgical System, a binocular telescopic camera lens system (0 or 30°) is attached to a high-resolution 3DHD camera, and together they are held on the main robotic manipulator arm. The da Vinci Xi Surgical System endoscope has "chip-on-tip" technology, where the digital image sensors are placed at the tip of the scope. The digital image information is then transmitted directly to the image processor. The binocular images are translated by the computer into a magnified 3D image when viewed at the surgeon console [2]. The robotic scope is either 12 mm (Si) or 8 mm (Xi) in diameter. On the Xi system, the 8 mm robotic endoscope fits through the standard robotic trocar, allowing for port hopping between trocars, giving surgeons the ability to have multiple vantage points in a single procedure.

### Patient cart (robotic arms and instruments)

The patient cart, consisting of the robotic arms and instruments, is draped and positioned alongside the patient table [3]. The patient cart has four arms. Robotic instruments have articulating joints (EndoWrist) near the tip that allow for wristed movement, providing seven degrees of freedom of movement for surgical tasks such

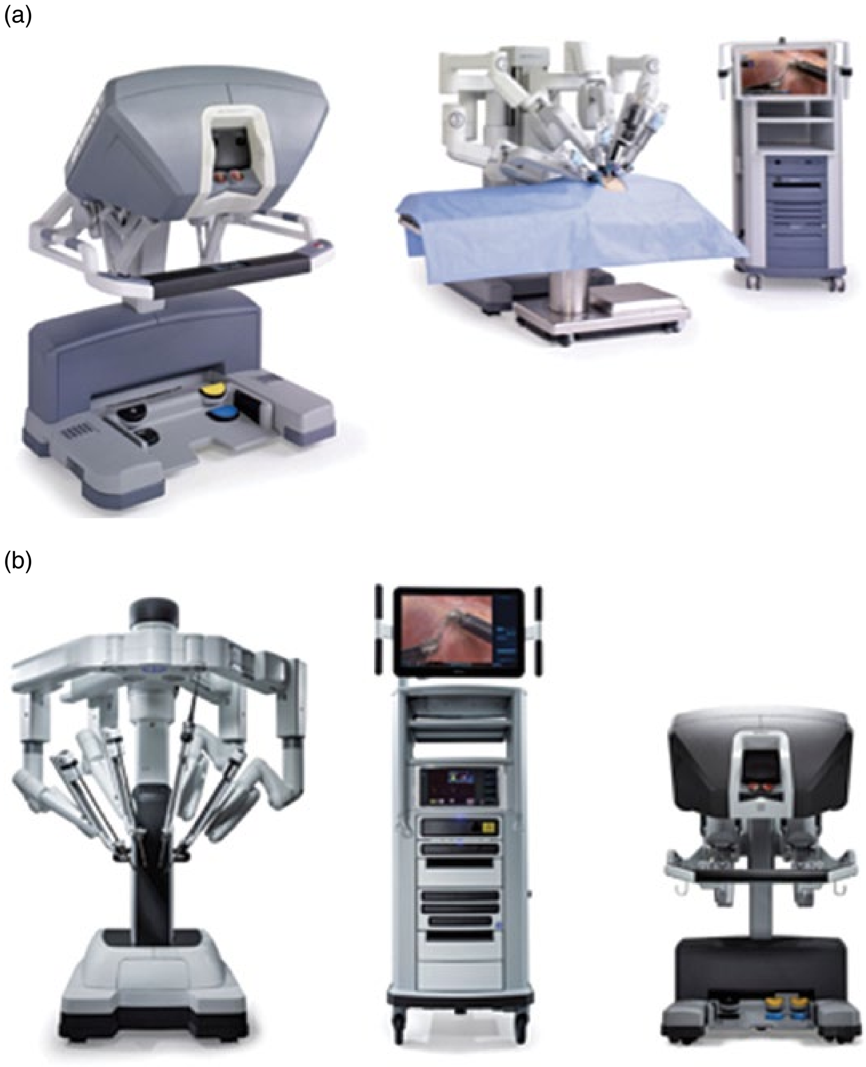

**Figure 81.1** The Surgeon Console, Patient-side Cart, and Vision System of the da Vinci Surgical System. (a) da Vinci Si Surgical System; (b) da Vinci Xi Surgical System.

as suturing and dissection. Robotic instruments are available with a variety of instrument tips in 5 or 8 mm diameter sizes.

The new da Vinci Xi™ Surgical System has four robotic arms attached to the mount of the patient cart, called the "boom." The Xi Surgical System has narrower arms and improved reach to minimize collisions between robotic arms. The endoscope can attach to any robotic arm through a robotic trocar, allowing flexibility in optimizing visualization of the surgical site. The "chip-on-tip" endoscope has a longer focal length and wider field of view. The rotating overhead boom allows for laser targeting and improved anatomical access from almost any position, which can help avoid the need for redocking and repositioning during surgeries such as nephroureterectomy.

## EndoWrist robotic instruments

The EndoWrist instruments are controlled by the surgeon at the console. The surgeon's finger movements are translated into movements of the instrument tips. The foot pedals can be used to toggle between instrument and camera movements, reset instrument movements (clutching) or initiate electrocautery [2]. Toggling between instruments allows a surgeon to control his or her own passive retraction using the third instrument arm. Clutching can also be performed using the finger clutch mechanism. If the robotic nondominant instrument is attached to cautery, care must be taken to avoid hitting the wrong foot pedal and causing thermal injury to the bowel or other structures [4].

Different EndoWrist robotic instruments offer different relative advantages for different procedures (Figures 81.2–81.5). Note: Some instruments may only be available on the Si or Xi system.

Commonly used EndoWrist monopolar cautery instruments include the Hot Shears™ monopolar curved scissors and monopolar cautery hook. Bipolar cautery instruments include the fenestrated bipolar forceps, Maryland bipolar forceps, PK™ dissecting forceps (Si only), and PreCise bipolar forceps (Si only), long bipolar grasper (Xi only), curved bipolar dissector, and microbipolar forceps. The robotic vessel sealer provides cauterization and coagulation of soft tissues and small vessels (less than 7 mm in diameter) using bipolar energy, with minimal thermal energy spreading, followed by cutting using the blade inside the instrument (see Figure 81.2).

Robotic grasper instruments include the, ProGrasp™ forceps, Cadiere forceps, double fenestrated grasper, and Cobra grasper (see Figure 81.3), as well as the tenaculum forceps and DeBakey forceps. In the nondominant hand, the fenestrated bipolar can be used for atraumatic dissection of vessels. However, the fine sharp tips of the Maryland bipolar forceps or PK dissecting forceps can be used for precise cauterization of small vessels and dissection of structures. The ProGrasp has no thermal energy but has the strongest closing force, making it a robust grasping instrument. In the dominant hand, the Hot Shears can be used for tasks such as cauterization, blunt and sharp dissection, as well as for tumor excision in cases such as robot-assisted partial nephrectomy [4]. The monopolar hook may be used for blunt dissection of vessels and dissection of tissue planes during extirpative procedures. Robotic ultrasonic shears are available, but they lack EndoWrist capability [5].

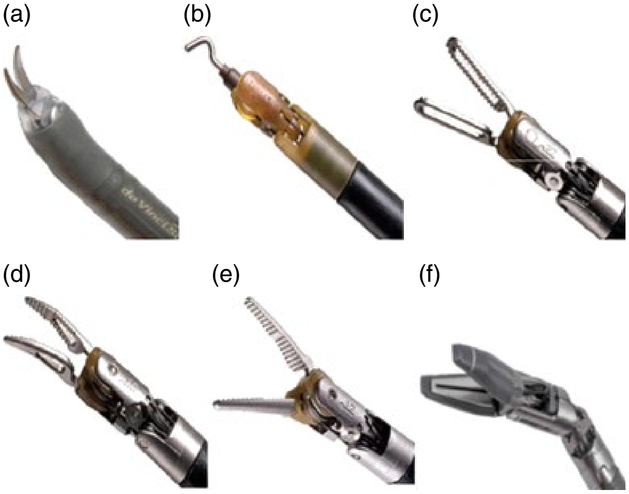

**Figure 81.2** EndoWrist monopolar and bipolar instruments. (a) Hot Shears (monopolar curved scissors); (b) permanent cautery hook; (c) fenestrated bipolar forceps; (d) Maryland bipolar forceps; (e) PK dissecting forceps; (f) vessel sealer.

Robotic needle drivers available for suturing include the large needle driver and mega needle driver (see Figure 81.4a). The surgeon may choose to use an EndoWrist grasping instrument, such as a ProGrasp, in the nondominant hand to economize instrument use. A SutureCut™ needle driver, available in both sizes, allows the console surgeon to cut sutures, but care must be taken not to accidentally cut the suture while handling it during suturing. Black Diamond needle drivers are also available for more precise suturing, such as the vascular anastomosis during robotic kidney transplant. The robotic Hem-o-lok™ clip applier can be useful for clipping vessels, particularly vessels at a challenging angle for the assistant to clip manually (see Figure 81.4b). Robotic clip appliers are available for large or medium–large

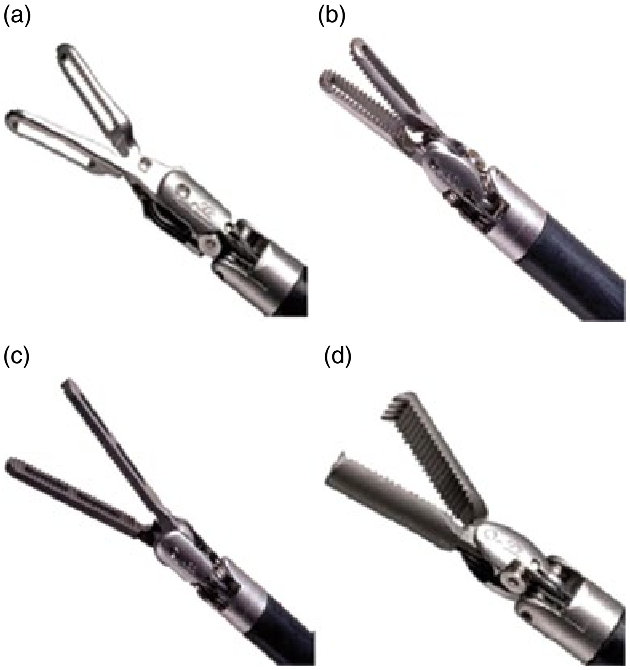

**Figure 81.3** EndoWrist grasper instruments. (a) ProGrasp forceps; (b) Cadiere forceps; (c) double fenestrated grasper; (d) Cobra grasper.

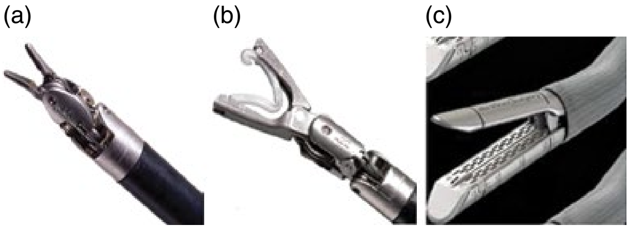

**Figure 81.4** EndoWrist robotic needle drivers, clip appliers, and staplers. (a) Large Hem-o-lok clip applier; (b) large needle driver; (c) robotic stapler.

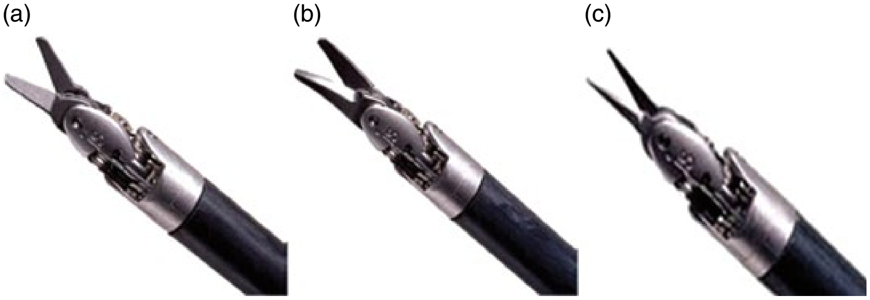

**Figure 81.5** Robotic athermal scissors. (a) Round-tip scissors; (b) curved scissors; (c) Potts scissors

Hem-o-lok clips or for small titanium clips. The clip is loaded externally and introduced by the assistant into the robotic port. The robotic clip applier holds a single clip, so having a second robotic clip applier can facilitate faster exchanges. Care must be taken not to inadvertently squeeze the fingers, as this may cause the clip to misfire. The robotic clip applier will accommodate 100 clip firings. The life of most other robotic instruments is 10 cases, after which the system will not allow the operational use of the instrument. An EndoWrist robotic stapler is also available for the da Vinci Xi Surgical System, allowing surgeon control and autonomy over positioning, gripping, clamping, and firing of the stapler through the surgeon console (see Figure 81.4c). The robotic stapler has fully wristed articulation. It can also detect whether the stapler jaws are adequately closed on the tissue for proper firing. EndoWrist staplers are available in size 30, 30curved, and 45 and available loads include white, blue, and green.

Athermal robotic scissors include round-tip scissors, curved scissors, and Potts scissors (see Figure 81.5).

### Third instrument arm

The third instrument arm can be utilized to provide retraction independent of the surgical assistant. The third instrument arm port is placed away from the other da Vinci instrument ports to minimize arm collisions. EndoWrist instruments used with the third instrument arm include the ProGrasp, and the double fenestrated grasper. For robot-assisted kidney surgery, the third-arm instrument can be used to lift the kidney anteriorly by placing it under the ureter [6]. This places the renal hilum on stretch, allowing two-handed dissection of hilar vessels.

## Robotic Ultrasound, Fluorescence Imaging, TilePro, and Robotic Bulldog Clamps

Robotic ultrasound probes have been developed that allow surgeon control of intraoperative ultrasound using a robotic grasper during robotic partial nephrectomy (Figure 81.6) [7]. TilePro is a multi-image video display mode of the da Vinci Surgical System that allows the surgeon to simultaneously view additional images, such as intraoperative ultrasound and preoperative CT images, as a picture-on-picture on the 3D console screen and assistant monitors. TilePro can be used during robot-assisted partial nephrectomy to localize tumors and to delineate margins of resection using intraoperative ultrasound without the need to leave the console to view external images [6]. The surgeon can switch back and forth from TilePro mode and can adjust the size of the image relative to the console view. The Firefly Fluorescence Imaging system may be utilized to assess vessels and tissue perfusion. After indocyanine green (ICG) dye is injected intravenously, the fluorescence mode is activated, causing near-infrared laser-induced fluorescence of the ICG and a corresponding color signal to perfused structures. The surgeon can toggle between white light and fluorescence modes. Robotic bulldog clamps have

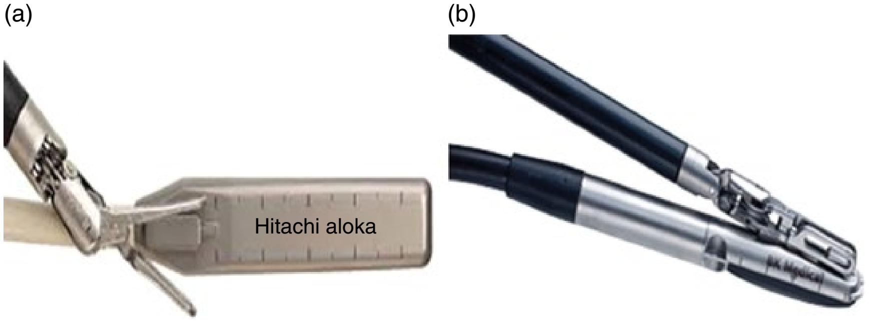

**Figure 81.6** Robotic ultrasound probes. (a) Robotically controlled ultrasound transducer (Hitachi-Aloka Medical America, Inc., Wallingford, CT, USA); (b) drop-in ultrasound transducer (BK Ultrasound, Luton, UK).

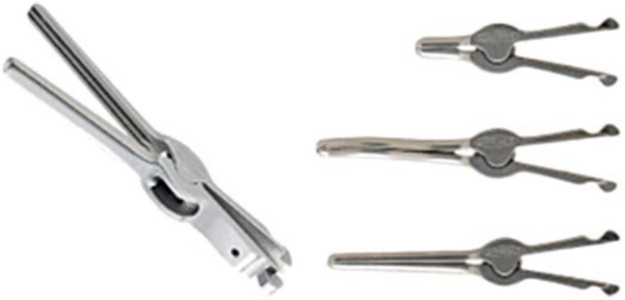

**Figure 81.7** Robotic bulldog clamps (Scanlan® Reliance Bulldog Clamps, Scanlan International, St. Paul, MN, USA).

also been developed that allow surgeon control over clamping of vascular structures (Figure 81.7). The robotic bulldog clamps can be applied using a robotic grasper, such as the ProGrasp, allowing the surgeon to have full articulation when applying and removing the clamp [8].

## Dual console capability

An optional second console available with the da Vinci Surgical System allows two surgeons to collaborate during a procedure. Surgeons can exchange control of the instrument arms and endoscope using the surgeon touchpad, while a built-in intercom system facilitates communication. The addition of a second console offers an environment for training and provides a platform to refine techniques and learn new procedures.

## Integrated table motion

Integrated table motion provides synchronized movement between the da Vinci Xi Surgical System and the operating room table (TruSystem® 7000dv, Trumpf Medical, Saalfeld, Germany), allowing the surgical table to be repositioned with the robotic arms still docked (Figure 81.8). This facilitates intraoperative adjustments to improve gravity exposure and access to target anatomy during multiquadrant surgeries, such as nephroureterectomy. This technology may also reduce the extent and duration of Trendelenburg positioning that a patient must tolerate during a robotically assisted urology procedure.

## Troubleshooting

Several studies have reported that the incidence of mechanical failure or malfunction with robot-assisted urologic surgery is low (0.4–4.6%) [5, 9–15]. Kim et al. reported that the incidence of instrument and mechanical failures was 1.9% [10]. Instrument problems include shaft injuries, broken or dislodged wires, nonrecognition or locking of instruments, unnatural motion because of a problem attaching to an adapter, or inadequate closure of tip. Instrument failure can be easily fixed in most cases by reseating the instrument or changing to a new instrument. Careful examination of instruments should be undertaken by the assistant before insertion. A dry lab experience for the surgical team to practice with the robotic instruments and the robotic interface is strongly recommended [16]. Mechanical failures or malfunctions of the da Vinci system may include the occurrence of recoverable or nonrecoverable faults originating from the surgeon console, patient cart, or vision cart. Maintenance of the system related to faults or damage can result in replacement of components on the surgeon console, patient cart, and vision cart, including replacement of damaged endoscopes. Zorn et al. reported four cases of mechanical failure; all cases were completed by delaying the procedures [11]. In the series of Lavery et al., 34 cases had mechanical failures or malfunctions; they were converted to open or laparoscopic procedure or cancelled [12].

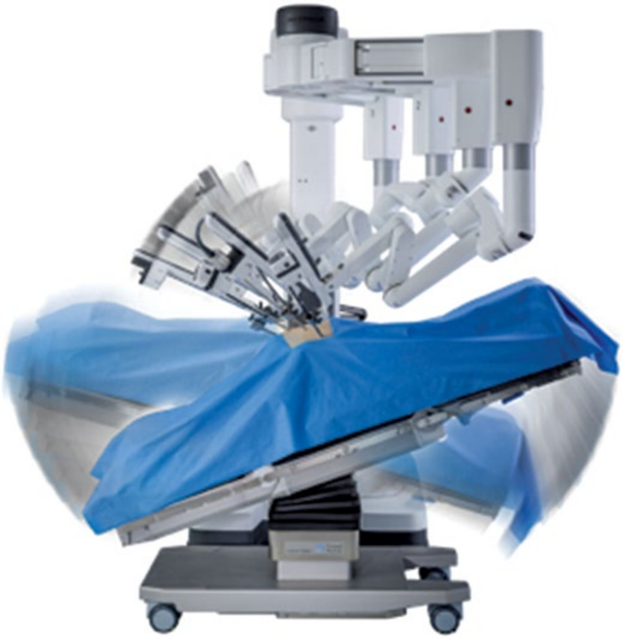

**Figure 81.8** Integrated table motion: combines da Vinci Xi Surgical System (Intuitive Surgical Inc.) and TruSystem 7000dv (Trumpf Medical), allowing ability to reposition operating table with surgical robotic arms docked.

The wider field of view of the da Vinci Xi endoscope may inadvertently result in surgeons bringing the camera closer to the tissue. The autofocus feature also may cause smoke between the camera and target tissue to be more visible. This may lead to increased frequency of smudging or fogging on the camera face. Troubleshooting tips to improve vision may include the use of the digital zoom feature to help bring the endoscope farther away from the target tissue, the use of the AirSeal® valveless insufflation system (Conmed, Utica, NY, USA) to allow for constant smoke evacuation, and the use of a thermos and hot water to clear the end tip camera and minimize temperature differentials along the shaft of the endoscope.

## Introduction

The evolution of laparoscopic and robotic surgery has expanded to accomplish more in reconstructive and complex urological procedures. For patients to get benefit from minimally invasive surgery (MIS) surgeons must first develop and gain proficiency with minimally invasive surgical skills required for these advanced surgeries. The skillset required for these reconstructive surgeries is very different from traditional open surgery; accordingly, both standard laparoscopic and robot-assisted procedures are associated with definite learning curves [1, 2].

Initially, laparoscopic reconstructive urologic procedures such as radical prostatectomy, partial nephrectomy, pyeloplasty, radical cystectomy, and urinary diversion were technically demanding, even in the most experienced hand; however, with the rapid improvement of laparoscopic instruments, and innovation of different clips, staplers, and suturing materials, intracorporeal suturing became much more efficient, minimizing patient morbidity while maintaining success rates and surgical efficiency. With the introduction of the da Vinci® surgical system (Intuitive Surgical, Inc., Sunnyvale, CA, USA) in the last decade, robotic surgery eliminated the early steep learning curve for novices, and at the same time improved the ergonomics of motion for experts, which may have implications for highly complex reconstructive procedures in limited workspaces (e.g. radical prostatectomy) [3].

Proper hemostasis is considered a critical key issue for successful reconstructive MIS. Precise tissue visualization during robotic and laparoscopic surgeries can be attained only in a bloodless field. Bleeding must be adequately controlled from the first attempt because it becomes more difficult to control in subsequent attempts. Prevention of bleeding requires from surgeons the timely and appropriate use of this innovative technology. A variety of major hemostatic modalities have evolved in the field of MIS (Box 82.1).

In this chapter we review in detail the mechanical methods commonly used in hemostasis and frequently applied during reconstructive MIS, namely "sutures, clips, and staplers."

## Sutures

During MIS, advanced surgical skills such as suturing and knot tying are required for many complex reconstructive procedures. Laparoscopic suturing requires skill and dexterity; the surgeon has an extremely restricted space to maneuver the needle and the 2D vision affords limited depth of perception. In addition, the loss of tactile feedback in laparoscopic surgery often represents a barrier to developing a proficiency in using needle drivers in a standardized way. In robotic surgery, tactile feedback is replaced by haptic feedback. Recent improvements in minimally invasive instrumentation have given surgeons and urologists easier methods of suturing and tying.

Tissue reapproximation is an important step during suturing, and many factors are important to make it reproducible, such as adequate port placement site, proper suture type and needle selection, understanding the relationship between the tissue, camera, and ports by the operating surgeon. Moreover, the use of mechanical suturing devices may improve efficiency and accuracy during suturing.

**Mechanical methods**

- Surgical clips
- Staplers
- Pretied suture loops
- Sutures
- Others:
  - Local pressure
  - Increased pneumoperitoneium

**Energy methods**

- Electrical energy
  - Monopolar electrosurgery
  - Bipolar electrosurgery
- Argon beam coagulator
- Ultrasonic energy
- Radiofrequency energy

**Hemostatic materials**

- Fibrin agents
- Collagen
- Synthetic sealants
- Oxidized regenerated cellulose
- Gelatin
- Flowable gelatin/thrombin

## Characteristics of suture materials

The choice of suture is determined by a balance between the type of surgery, the characteristics of different anatomical layers that requires reconstruction, and the characteristics of available suture materials. Certain types of suturing materials can be particularly difficult to work with due to their stiffness and tendency to resist deformation, and forming the slipknots to close wounds and surgical incisions requires great skill. The characteristics of various suture materials are summarized in Box 82.2. Recently, an absorbable unidirectional barbed suture (V-Loc™180, Covidien, Mansfield, MA, USA) (Figure 82.1) has been introduced and has gained popularity in reconstruction of the urethrovesical anastomosis during radical prostatectomy. The unidirectional barbed suture has many advantages: it makes the anastomosis easier in a shorter time period compared to the nonbarbed monofilament suture, it improves tissue handling and decreases the tension placed by the assistant on the running suture during the anastomosis while re-approximating the urethra and bladder neck, it prevents slippage once the bladder neck and urethral tissue are re-approximated, and the tissue stays in place and does not migrate. In addition, it eliminates the risk of erosion of the Lapra-Ty® clips used to secure the posterior urethral reconstruction [4, 5].

## Suture length

The length of the suture used during MIS varies and depends on its type and application. For extracorporeal knot tying, maintaining a long suture length (80–120 cm) is required to allow passage of the suture ends outside the trocar. On the other hand, intracorporeal knot tying requires a shorter length. For example, 8–10 cm length is adequate for simple interrupted sutures. For running sutures an extra 10–12 mm suture length is needed for each additional stitch. Running locking sutures require additional 20–25 mm length per stitch. Adequate length should be maintained for knot tying at the end of suturing to avoid stress on the reconstructed tissue [6].

## Needle description

The surgical needle has three major parts: the tip (or needle point), the needle itself (body), and the swage (needle back where the suture is attached). The diameter (the distance between the needle point and the swage) is known as the chord length. The needle may be curved, with a radius of between 1/4 and 5/8 of a circle, or straight. The tip may be triangular with either conventional cutting (sharp edge on the inner arc) or reverse cutting (sharp edge on the outer arc). The latter has less chance of tissue tearing during suturing. The needle body may be flattened to facilitate grasping it and to reduce twisting during suturing.

When using a curved needle, it is best to grasp it halfway along the needle arc for better suture control. Likewise, when using a straight needle, placement of the needle holder in the middle allows for more precise needle placement and suturing. Successful needle holding requires alignment of both the tissue and needle.

## Needle entry

Successful needle entry into the abdominal space is the first step of suturing. The commonest entry route is through the trocar lumen, which requires adequate knowledge of needle sizes, shapes, and different trocar diameters. Grasping the needle 2 cm proximal to its swage facilitates its passage together with the needle driver into the abdominal cavity through the trocar, and minimizes risk of trocar valve mechanism damage.

Needle entry through the abdominal wall is an uncommonly used route. This technique is used particularly when a stay suture is required for temporary traction during certain reconstructive urologic surgery, such as

**Box 82.2 Suture material characteristics and properties.**

### Absorbable vs. nonabsorbable

*Absorbable sutures*

Examples: surgical gut, polyglactin 910 (Vicryl, Polysorb®), poliglecaprone 25 (Monocryl®), polydioxanone (PDS II®), polytrimethylene carbonate (Maxon®), and glycomer 631 (Biosyn®).

Absorbable sutures lose most of their tensile strength within 60 days. They are usually used as deep sutures in laparoscopic and robotic surgery (e.g. partial nephrectomy, myomectomy or intestinal anastomosis).

*Nonabsorbable sutures*

Examples: nylon (Ethilon®, Dermalon®, Surgilon®, Nurolon®, Nylene®), polybutester (Novafil®), polypropylene (Prolene®, Surgilene®, Surgipro®), silk (Dysilk®), polyester (Dacron®, Mersilene®, Ethibond®), and GORE-TEX® suture.

Nonabsorbable sutures are used for reconstructive surgery (e.g. sacrocolpopexy or Burch coloposuspension), where manual removal of suture postoperatively is not required.

### Multifilament vs. monofilament

Multifilament sutures are handled more easily and tie well in laparoscopic and robotic surgery. However, they carry an increased risk of infection. Monofilament sutures are more difficult to handle and to knot securely, but have a lower infection risk.

### Tensile strength

Tensile strength depends on the size (thickness) of the suture in use. A smaller suture with adequate tensile strength is preferred by surgeons since it decreases foreign body load on the tissue. For example, 3-0 suture is a thick, strong suture used for fine surgery in laparoscopic surgery (e.g. renorrhaphy during partial nephrectomy or vesicourethral anastomosis during radical prostatectomy), while 6-0 is a thinner and weaker suture which is used for ultrafine surgery (e.g. fallopian tube anastomosis).

### Plasticity and elasticity

Plasticity is defined as the ability to retain strength and length after stretch, while elasticity is the ability to regain original length after stretch. Laparoscopic instruments may cause tissue damage because lack of tactile feedback, therefore surgeons should respect suturing as much as they can in order to reduce postoperative edema without tissue cutting and maintain epidermal approximation after edema resolution.

### Ease of handling and knot security

Ease of handling and knot security are determined by a number of related properties:

- Sutures with low coefficient of friction usually slide well through the tissue, but the knot may unravel easily
- Sutures with high memory will return easily to their original position and are difficult to use. Prolene suture is strong, difficult to tie, and has lower knot security
- High pliable sutures are more easily bent and can be handled well with good knot security during laparoscopic surgery (e.g. Vicryl)

### Tissue reactivity

The degree of tissue inflammatory depends on the suture type. It is high for natural sutures, such as silk and catgut, and low for synthetic sutures, such as nylon.

pyeloplasty. Straight needles pass through the abdominal wall, then the target tissue, and finally through the abdominal wall again and are clamped outside the abdominal cavity to facilitate traction and countertraction. The application of this technique obviates the need for extra trocar insertion for retraction purposes during surgery.

## Suturing instruments

### Laparoscopic needle drivers

A variety of laparoscopic needle drivers are available in several different configurations and can be used based on surgeon preference or type of surgery. Needle driver jaws are divided into four main categories: straight, curved right, curved left, and self-righting. Recently, needle drivers with an articulating tip have become available; these can be controlled by angling the instrument's handle. Theoretically, such devices might offer greater maneuverability and efficiency when compared to nonarticulating types, but they have a steeper learning curve [7]. Needle control and the performance of precise freehand laparoscopic suturing is determined by the needle stability within the driver. An ideal needle driver is characterized by the following properties: it is light with an easy unlocking mechanism, and provides firm grip when driven through the tissues in a direct path [8].

### Robotic needle drivers

The various features of robotic surgical systems, such as stereoscopic 3D vision, magnified view, wristed instruments, and tremor filtration, are presumed to improve

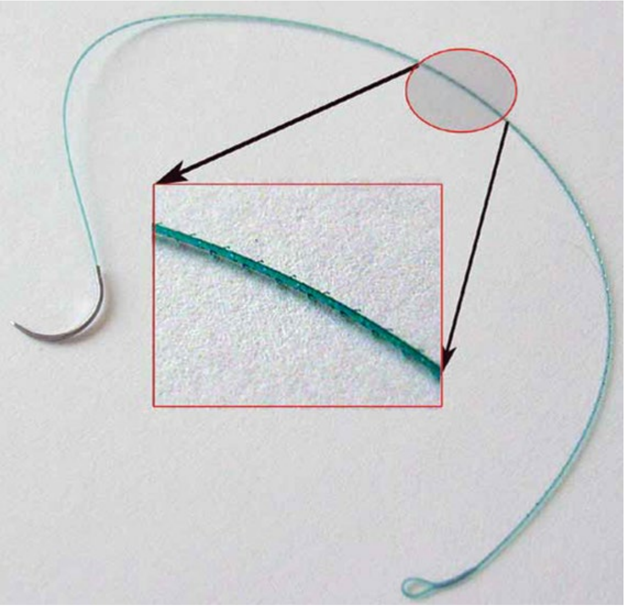

**Figure 82.1** V-Loc™ 180 suture.

performance in laparoscopic tasks. The increase in degrees of freedom for the instrument's tip (seven degrees of freedom) and 90° of articulation which are used inside the human body has led to better instrument tip control in a more natural and fluid flight path (Figure 82.2). The net result is increased dexterity with easier and more accurate suturing in a minimally invasive fashion. Various types of robotic needle drivers are available, including "fine micro-forceps used for suturing the fine structures during cardiovascular surgery and during nerve anastomosis, and a mega-needle driver used for suturing of larger and thicker tissues" (Figure 82.2). The SutureCut™ needle driver is a new needle driver provided with an integral cutting blade for efficient cutting of suture after knot tying.

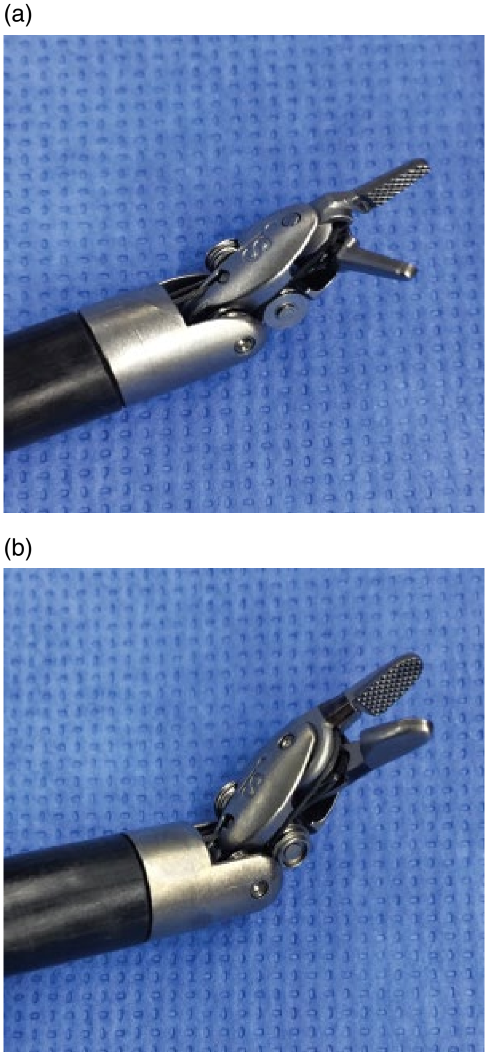

**Figure 82.2** Two types of robotic needle drivers from Intuitive Surgical, Inc.: (a) fine micro-forceps and (b) mega-needle driver.

## Classifications of knots

A variety of knot types are used in laparoscopy. The most common ones are listed in Box 82.3.

### The half knot

For this knot both ends of the suture must be pulled in opposite directions in the same plane with uniform tension. It is incomplete, unreliable, and has a tendency to untie.

### The slipknot

For this knot each thread has a different role; one remains passive and inactive during the tying process, while the other is the active thread which forms the knot by wrapping around the passive one. Similar to the half knot, the

**Box 82.3 Classification of knots used in minimally invasive surgery.**

**Basic knots**

- Half knot: both ends must be pulled in opposite directions in the same plane with uniform tension
- Slipknot: one thread remains passive, and the active thread forms the knot by wrapping around it

**Complete knots**

- Square knot: sequences of two identical half knots
- Surgical knot: blocking sequences of half knots
- Slipknot: blocking sequences of slipknots

slipknot is incomplete and unreliable; it is also an asymmetric knot that cannot maintain approximation of wound edges.

### Blocking sequences

This is a series of half knots and/or slipknots which provide maximum grip to the knot. Both the half knot and the slipknot are considered the cornerstones of the knot (e.g. square, surgical, or slip), which is formed from blocking sequences of two or more slipknots and/or half knots.

## Classification of suturing techniques

Suturing techniques during laparoscopic suturing are divided into two types: intracorporeal and extracorporeal suturing.

### Intracorporeal technique

The intracorporeal knot is a challenging technique, especially for junior laparoscopists, and generally has a steep learning curve. During intracorporeal suturing, the knot is made inside the abdominal cavity using two instruments – either two needle drivers or one needle driver and one assistance forceps, depending on surgeon preference. For easy interrupted suturing, it is vital to keep the tail at the terminal end relatively short before tying a knot. This is because a long tail suture may be difficult to locate if adhered to the abdominal viscera. When this occurs, it requires further cinching movements to bring the knot down to the target tissue, which makes knot tying more difficult at the other end of the suture line. Meanwhile, the running is difficult during the tying of the second knot because of the short remaining suture length available while maintaining constant tension on the first knot. An example of a commonly used intracorporeal knot is the square knot. In a certain circumstances it becomes very useful for the surgeon to know how to convert a square knot into a sliding knot when undue tension is applied to the target tissue. After placing two half hitches in the suture, no further cinching down to the tissue is needed. Instead, the free suture end is grasped and tensioned, converting the square to a slipknot, while pushing the knots towards the target tissue with the free instrument. In order to secure the knot properly, additional half hitches may be applied.

### Extracorporeal technique

During extracorporeal suturing, the knot is made outside the abdominal cavity, then it is pushed intracorporeally using a knot pusher, such as slipknot or Roeder's knot pusher. Various types of extracorporeal knots are available: nonsliding "static" knots (e.g. square knot, half hitches, and revo knot) and sliding knots (e.g. hangman's knot, Roeder knot, Lieurance Modified Roeder knot, Meltzer's knot, Tennessee slider, Tayside's knot, Weston slipknot).

The general drawbacks of the extracorporeal technique are as follows:

- Unlike the intracorporeal knots, it places undue tension on the tissue during tying of the knots which may become macerated and tear the delicate tissues apart.
- Loss of pneumoperitoneum may occur, which can be alleviated by placement of a finger over the trocar mouth during the tying of the knot.

To our knowledge, the square knot and the Roeder's knot are the most common types of extracorporeal knots. They are described below.

#### *Square knot*

This is formed of alternating half knots and then cinched using the knot pusher by advancing it through the trocar down to the tissue. A surgical knot is placed to maintain adequate tension locally at the tissue level while the second half knot is being performed. Tension is maintained on the free ends of the suture, while advancing the knot pusher. To ensure a true square knot the alternating half knots need to be in opposite directions.

#### *The Roeder slipknot*

This was the first knot described in laparoscopic surgery. Roeder's knot is easy to assemble and place, secure, and is a cost-effective alternative to intracorporeal suturing and staples during laparoscopic surgery. Its advantage over the square knot is that the entire knot is entirely formed before advancing it into the intracorporeal space. It may be useful in the ligation of somewhat bulky tissue (e.g. the dorsal venous complex) owing to its slip feature. To form the knot, one short limb (the post) and one long limb (the loop) are made, and then a half hitch is placed. The loop is thrown around the post several times depending on the suture material used (braided and gut-based sutures require 3–5 loops while monofilament sutures require 5–7 loops). The loop is then thrown around both limbs and past the tail of the loop limb between the last two loops. Finally, the loop is thrown only around the post limb. The knot is tensioned and pushed into the joint with a knot pusher on the post limb. Once the initial knot is in position, additional half hitches may be placed for security.

## Knot-tying devices

Knot-tying devices may be used to secure the ends of both running and interrupted sutures.

### The Lapra-Ty clip

The Lapra-Ty® (Ethicon, Cincinnati, OH, USA) is an absorbable one-piece clip molded from the polymer poly(p-dioxanone) (Figure 82.3a). It is delivered by a reusable 10 mm clip applier (33 cm or 45 cm length). Clips are designed as anchors and secure each end of a single strand of 2-0, 3-0, or 4-0 coated Vicryl® (polyglactin 910) suture for soft tissue approximation for a period of up to 14 days. It eliminates the need for intracorporeal knot-tying and frees the bedside assistant from keeping traction on one side while making the opposite half of the anastomosis. The Lapra-Ty clip provides a stable tension on the suture and allows for creation of a safe, watertight anastomosis (e.g. during vesicourethral anastomosis of radical prostatectomy) (Figure 82.3b). Suture lines tied with a Lapra-Ty clip can be further cinched by pulling the suture and applying an additional clip under the previously placed one. This provides a greater flexibility to the surgeon in securing suture lines to the desired level of tension [9]. Another advantage of the Lapra-Ty clip is its usefulness in shortening the time needed to complete time-sensitive tasks such as renorrhaphy during partial nephrectomy (Figure 82.3c). In addition, in the case of a short remaining suture length making it difficult to tie the knot, Lapra-Ty could be applied easily. It should be borne in mind that because of a concern regarding the risk of developing an inflammatory reaction, it is better to apply it on the final knot of running sutures.

### The Ti-Knot TK5

The Ti-Knot TK5® (LSI Solutions, Rochester, NY, USA) is another “knot-tying” device. It delivers titanium knot “non-reactive material” to mechanically fasten a suture and automatically cuts away excess suture in one step. It requires an extracorporeal loading of the suture into the device, and both ends of the suture must be maintained at length to allow the instrument to be loaded extracorporeally. Once loaded, the device is introduced intracorporeally, the desired tension is achieved, and a titanium knot is deployed, which locks the suture in place. The Ti-Knot titanium knot can be applied safely during laparoscopic ligation and control of the dorsal vein complex [10] and renal arteries [11]. However, the additional costs related to the use of this disposable device preclude its widespread use.

## Ancillary suturing devices

Since laparoscopic suturing is a technically demanding task, additional instruments have been developed to facilitate suturing.

### The Endo Stitch

The Endo Stitch™ (US Surgical, Norwalk, CT, USA) suturing device was developed to facilitate suture

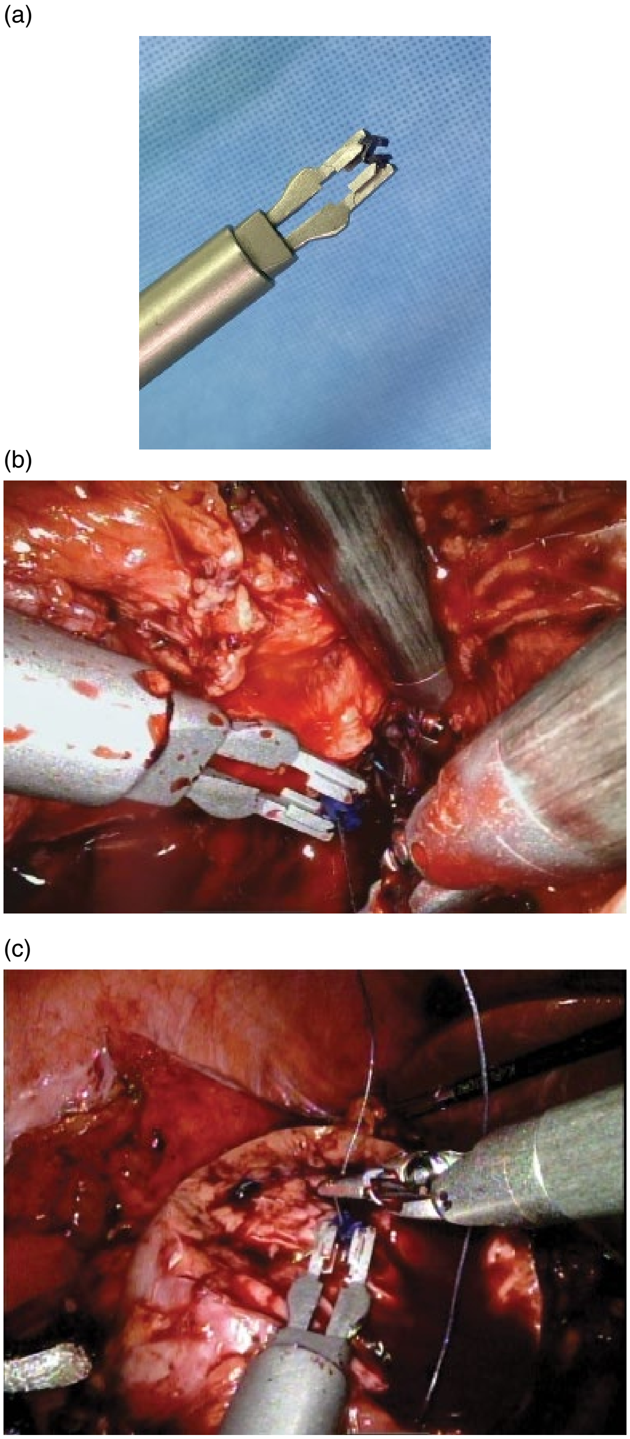

**Figure 82.3** (a) The Lapra-Ty® (Ethicon) and its metal applicator. (b) Application of Lapra-Ty clip at the terminal end of a running 3-0 barbed suture (V-Loc 180) after complete vesicourethral anastomosis during Retzius-sparing robot-assisted radical prostatectomy. (c) Application of Lapra-Ty clip at the terminal end of a running 3-0 Vicryl suture for renorrhaphy during right-side robot-assisted partial nephrectomy.

placement and knotting of advanced reconstructive laparoscopic procedures (e.g. laparoscopic dismembered pyeloplasty and bladder neck suspension) by passing a small needle with its secured suture back and forth between its jaws. After each pass, the needle is locked temporarily in place until the instrument handle is squeezed again to transfer it to the other arm. A 10 mm port is required for its use. It reduces the amount of time needed for placement of stitches and knot tying compared to conventional suturing [12, 13]. It has some disadvantages: its short needle cannot pass through thick tissue so cannot be used for reconstructive surgery requiring large bites, such as renorrhaphy during partial nephrectomy; in addition, it increases the cost of the case as it is disposable and needs reloading.

#### The Suture Assistant

The Suture Assistant® (Ethicon) and Reload Units are used in minimally invasive surgical applications. The Suture Assistant is a 5 mm sterile, single-patient-use instrument designed to secure suture knots intracorporeally. It is disposable and uses dedicated reloads.

#### The Sew-Right SR5

The Sew-Right® SR5® (LSI Solutions, Rochester, NY, USA) is a reloadable 5 mm suturing device that uses two built-in needles to place a simple suture precisely through even a relatively thick tissue. Its needle passes parallel to the instrument shaft. With a single squeeze of the lever against the handle, the first needle passes through the tissue. The needle automatically captures the suture and pulls it back through the tissue to complete the driving of the suture. The second needle is then selected to take a second bite. Once the suture is complete, the instrument is disengaged from the tissue, and a titanium knot is passed onto the suture to secure it. It is a disposable instrument and only a single simple suture is placed every load.

#### The QuikStitch

The QuikStitch® (Pare Surgical, Englewood, CO, USA) is a mechanically assisted suture device of various sizes 3, 5, 10, and 12 mm, where the needle driver passes through a spool containing a pretied knot. Both the device and needle drivers are reusable, making it commercially more appealing than some other designs. Different needle shapes (e.g. straight or curved) and suture types (e.g. absorbable and nonabsorbable) are available [14].

## Clips

Because of the technical difficulty in achieving ligation with sutures, clip systems are the preferred mechanical method for sealing blood vessels and ligation of small structures such as ducts during minimally invasive laparoscopic and robotic surgery. Clips are also faster. There are two main types of clips commonly used in our practice: metallic titanium clips and nonmetallic clips (Hem-o-lok).

### Endoscopic clip appliers

Clip appliers are classified into various categories: single-load or multiload, and disposable or reusable "multiple uses" (Figures 82.4 and 82.5). Both types of applier can carry various types of metallic or nonmetallic clips.

#### Single-load "reusable" clip applier

The single-load reusable clip applier has been the standard clip applier used in open and laparoscopic procedures. High-quality reusable clip appliers are available from several manufacturers. They have the advantage of 360° rotational ability and low cost, but are not without disadvantages:

- They are slower because the instrument must be removed and reloaded for each clip application, which is an important limitation in emergency situations.
- There is a tendency for the loaded clips to dislodge from the jaws when passing into a trocar or through the abdominal cavity.

#### Multiple-load "disposable" clip applier

The majority of clip appliers nowadays are multiloaded and disposable, carrying from 15–30 clips per unit. They are available in many models. This type of clip applier can save time and be helpful during emergency when clipping a bleeding vessel because of its ability to fire multiple clips without exiting the abdominal cavity to reload. Other characteristics include the following:

- They eliminate the risk of dislodging a clip from the applier's jaws while being passed through the trocar valve.
- Closure of the clips occurs from distal to proximal (Figure 82.4c). This ensures that the desired vessel or structure is contained within the clip, and prevents it from being pushed forward and out of the opposing arms of the engaging clip.
- The applier shaft gives 360° rotational capability (Figure 82.4a). This important feature allows for ergonomic hand positioning, which facilitates instrument use and improves the accuracy of clip placement.
- Some clip appliers have the ability to reload clips automatically, thus eliminating another step in the clip application. Immediately after a clip is placed, another one is advanced into firing position. This is an advantage over other clips which require manual reloading through partial closure of the firing handle or that have

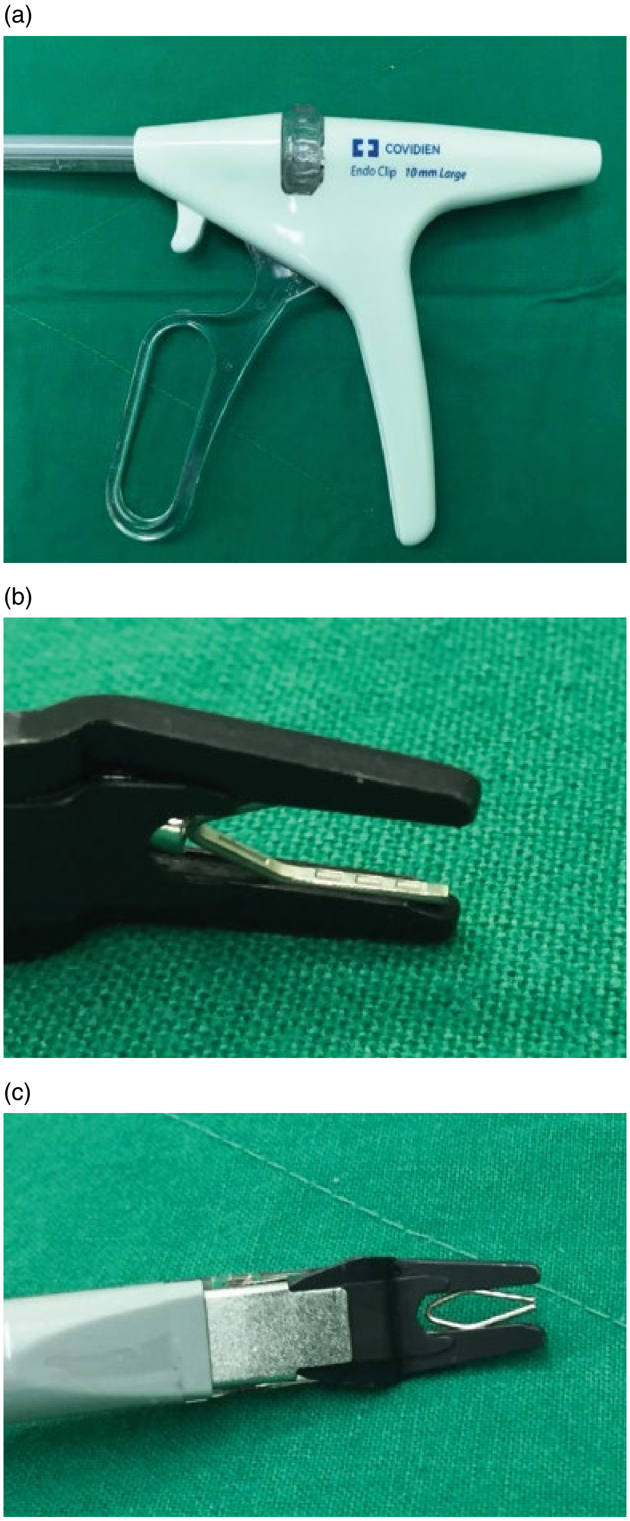

**Figure 82.4** Multiple-load "disposable" clip applier (10 mm Endo Clip™ II, Covidien) with its metallic titanium clips. (a) The applier has 360° rotational ability and is loaded with 10 mm clips. It has a separate trigger that reloads a clip when pulled. (b) The titanium clip has ridges and depressions along its internal surface. (c) Closure of the clip occurs from distal end first.

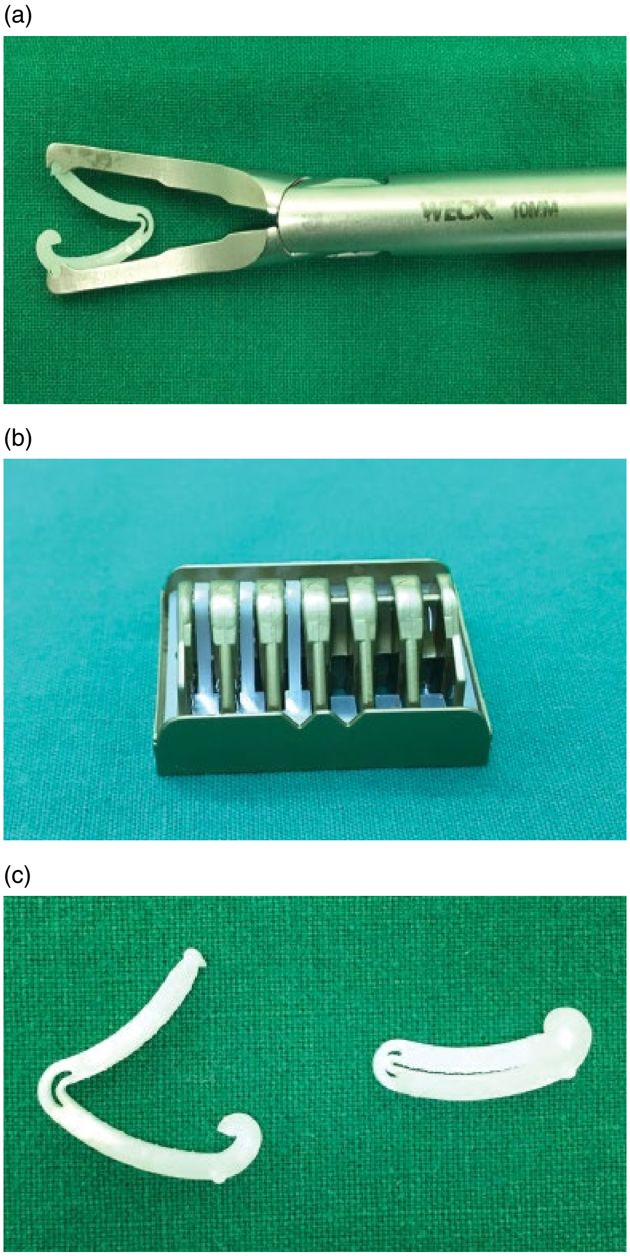

**Figure 82.5** Single-load "reusable" metallic clip applier and the Hem-o-lok® (Weck®, Teleflex Medical, Morrisville, NC, USA). (a) The applier has 360° rotational ability and is loaded with a 10 mm clip. (b) The cartridge contains six clips. (c) The Hem-o-lok™ clip has a lock-engagement mechanism and teeth within its jaws.

a separate trigger that reloads a clip when pulled (Figure 82.4).

- A visual indicator is usually incorporated to show the bedside assistant staff the number of remaining clips after each use.
- To avoid inadvertent injury to a blood vessel or other structure, most appliers are equipped with an automatic lock feature preventing closure of the jaws when the device is out of clips.

- The diameter of the shaft depends on the clip size. Shafts of 5 mm are available for medium clip appliers. For medium–large and large clips, the shaft sizes are 10 mm and 12 mm, respectively.

The automatic reloading clip applier has a potential disadvantage in that the tips of the applier cannot be used as a dissecting instrument without dislodging the loaded clip into the field during dissection.

## Nonmetallic clips

The Hem-o-lok™ (Weck Closure Systems, Research Triangle Park, NC, USA) was introduced in 1999. It is a nonabsorbable radiolucent polymer clip, which has a lock-engagement mechanism and teeth within its jaws (Figure 82.5). There are four sizes of Hem-o-lok clips and appliers (M, ML, L, and XL), ranging from 2 mm to 16 mm. This engaging clip latching mechanism enables the surgeon to feel the transmitted clip closure through the laparoscopic applier via tactile feedback. This design provides better security when the clip is applied to the tissue, and once engaged it is quite difficult to dislodge, even when operator tries to remove them using a purpose-built Hem-o-lok clip remover. The use of Hem-o-lok has been reported to be safe for renal pedicle ligation during laparoscopic renal surgery [15]. Moreover, there are published reports in favor of its application during minimally invasive general surgery procedures such as appendectomy, cholecystectomy, and splenectomy [16–18]. The 5 mm Weck clip can be used during renorrhaphy of partial nephrectomy, using the sliding technique (Figure 82.6).

### *Complications of Hem-o-Lok clips*

Complications are uncommon and only few cases reports have been published. Migration of the clips, although a rare problem, can cause serious complications (e.g. bowel obstruction, bladder or bowel perforation, stone formation and bladder neck contracture) that may necessitate further surgical intervention [19–23].

### *Contraindications*

Hem-o-lok clips are contraindicated for ligation of the renal artery during laparoscopic living-donor nephrectomy. This contraindication has been added to the instruction for use by the manufacturer Teleflex Medical in 2006, after receiving 15 medical device reports of 12 injuries and 3 deaths. Furthermore, an additional 3 kidney donor deaths have been reported since the contraindication was issued [24, 25]. Although there are published journal articles which support the continued use of Hem-o-lok clips for the renal artery ligation during laparoscopic living-donor nephrectomy [26], the US Food and Drug Administration warns healthcare providers regarding this contraindication because of its potential life-threatening complications. The basic principles of the Hem-o-lok and other clip types during their applications for vascular ligation are illustrated in Box 82.4. The failure rates of Hem-o-lok clips may be negligible when considering these principles during surgery [15, 27].

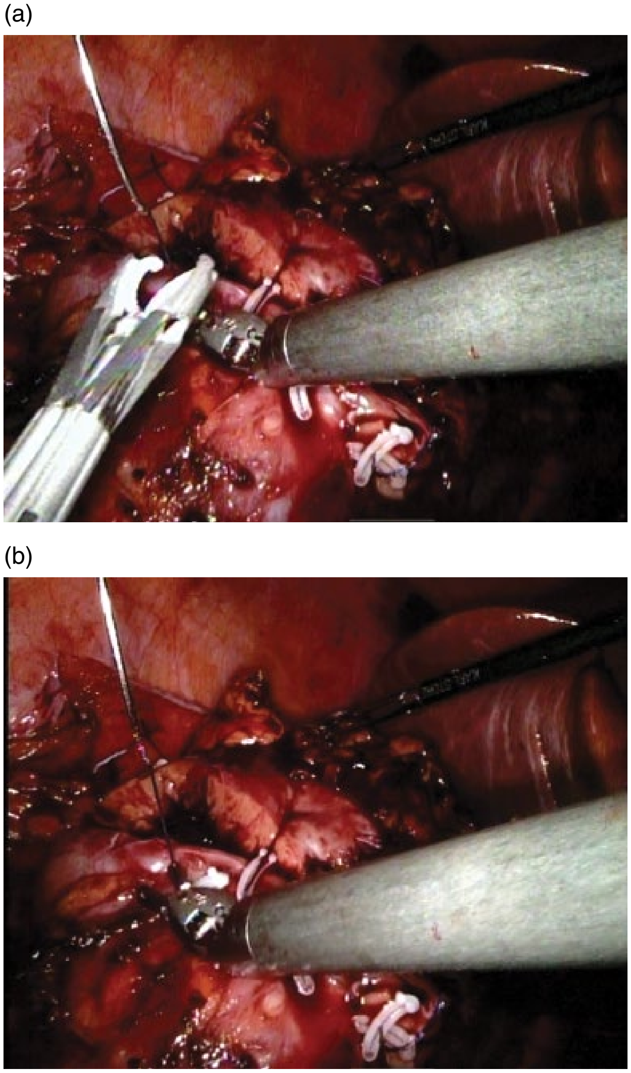

**Figure 82.6** Use of 5 mm (Weck Hem-o-lok Auto Endo5, Teleflex Medical) in the sliding-clip renorrhaphy technique during robot-assisted partial nephrectomy. (a) Application of the Weck to 3-0 Vicryl suture and (b) cinching the thread through the Weck with the robotic needle driver.

## Metallic clips

Titanium clips are nonabsorbable clips available in both straight and right-angled variations. They are commonly carried on the multiple-load disposable devices.

**Box 82.4 Basic principles of clip application during minimally invasive surgery.**

- Complete circumferential dissection of the targeted vessel or structure to develop a wide space to place clips and to prevent inadvertent clipping of nontarget tissues
- Select proper clip size
- The curved tip of the clip must be visualized around and beyond the vessel, and then slid up or down the vessel into optimal position before firing
- Tactile snap should be felt when the clip is engaged
- Adequate visual stump length should be maintained below the most proximal clip
- At least 2–5 clips seem mandatory for safe control of vessels sized ≥3 mm
- For smaller vessels, typically 1–2 clips are used on both the proximal and distal ends of the area to be divided
- Avoid cross-clipping
- The clip should be applied perpendicular (90°) to the vessel
- Unlike metal clip application, do not squeeze the clip handles too hard
- Avoid keeping the applier within the abdomen when not in use
- The same angle should be maintained to avoid pulling of clips during removal of applier
- Ensure that the clip does not catch on the loading mechanism to avoid placing undue shear force on the target vessel
- The applied clip may be pulled back and out of position if undue traction is inadvertently transferred to the clip
- The tips are sharp and may cause laceration of nearby vessels (e.g. renal vein)
- Before transection of vessels, check the ligation site to ensure security and proper closure
- During transection of vessels, partial division is performed initially before complete transaction to ensure proper hemostasis
- Avoid using electrocautery to divide the vessels in order to avoid late tissue necrosis and clip failure
- If a clip is misplaced, Maryland or DeBakey forceps may be used to slowly remove it by backing it straight off the clipped vessel or tissue

Modified from Ponsky et al. [15].

Titanium clips are available in various sizes ranging from 5 to 12 mm and have ridges and depressions along the internal surface that is in contact with the tissue (Figure 82.7). This pattern decreases the likelihood of them slipping off due to either subsequent nearby tissue dissection following ligation or increased vascular pressure within the clamped vessel.

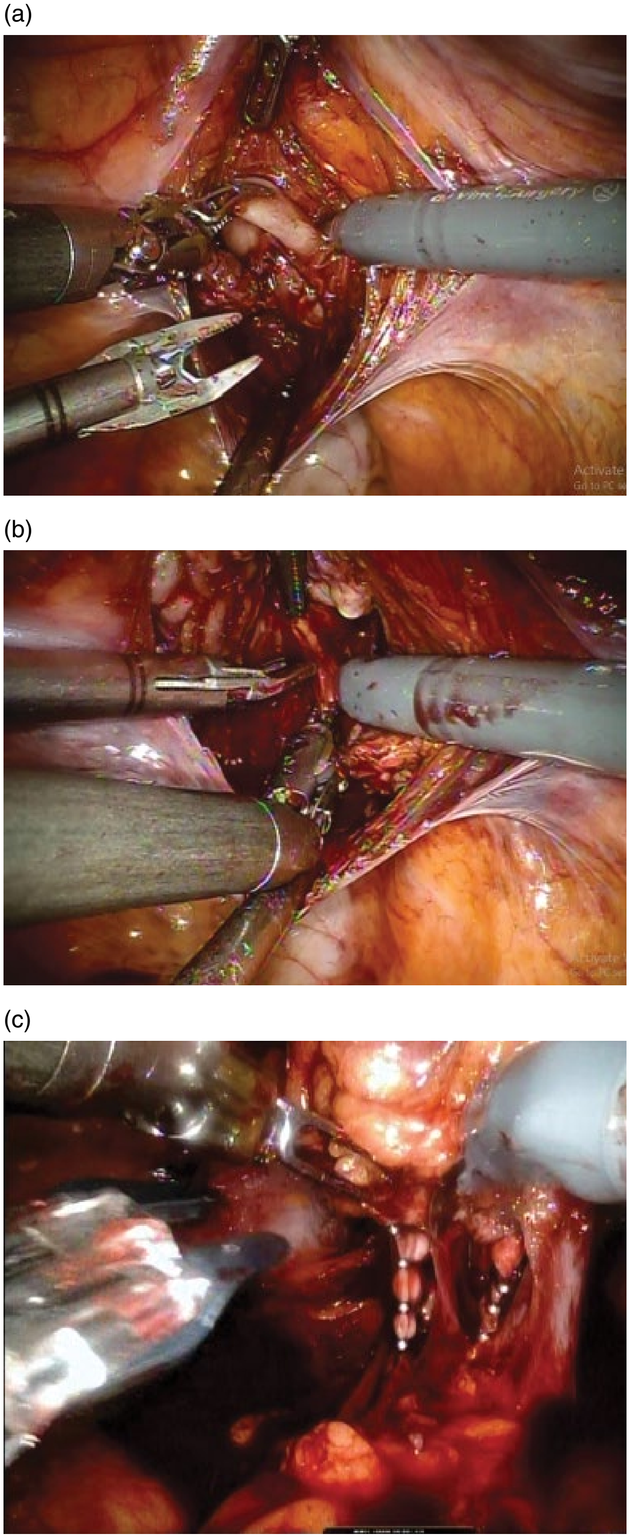

**Figure 82.7** Use of 5 mm titanium clip (LIGAMAX™ 5 EL5ML, Ethicon) during Retzius-sparing robot-assisted radical prostatectomy. (a) Ligation of the right vas deferens before its division and (b) securing the right neurovascular bundles during nerve-sparing step. (c) Application of multiple 10 mm titanium clips (Endo Clip II) during robot-assisted partial nephrectomy for clamping the main and accessory renal arteries.

Titanium clips are most commonly used to clip small-to-moderate sized structures, although they may be used to clip vessels of any size. For example, multiple titanium clips may be used to clip large vessels such as the main renal artery during laparoscopic or robotic nephrectomy when the stapler is not available or cannot be applied (Figure 82.7c).

### Tissue reaction to endoscopic surgical clips

The foreign body reaction profiles of clips used in securing vessels and sutures depend on the materials they are made of. Foreign body reactions correlate to the duration of suture absorption, developing at the end of the absorption processes [28]. Although Hem-o-lok and titanium clips are nonabsorbable materials, they have a low level of foreign body reaction. This was studied in rats, comparing tissue reaction to absorbable endoloop, nonabsorbable titanium staples, and polymer Hem-o-lok clips after laparoscopic appendectomy. There were no significant differences in histopathological changes observed on the 14th postoperative day across the three groups. On the 28th postoperative day, it was found that mild and moderate inflammation was more frequent in the endoloop than in the titanium stapler and Hem-o-lok groups [29].

Klein et al. [30] reported that there were no significant differences in fibrous tissue formation at any time between the absorbable polymeric surgical and titanium clips in the rat model.

## Staplers

Surgical staplers are widely used in various urological surgeries, such as radical nephrectomy, nephroureterctomy, radical cyctectomy, and urinary diversion. They are primarily used for medium and large-sized vessel ligation and division (e.g. renal hilum, bladder pedicle, or bowel mesentry), or reapproximation of visceral structures (e.g. small intestine or bladder) for anastomotic purposes. These instruments are vital to prevent major hemostatic complications.

### Characteristics and mechanism of stapler action

Staplers allow for rapid tissue ligation with or without division by deploying metallic staples arranged in several parallel rows. The metallic staples are laid in a brick-like intercalated pattern which allows them to overlap from one row to the next.

Endoscopic linear cutting devices (Endo GIA™, Covidien) typically use two sets of three parallel rows of hemostatic staples on each side and produce a linear incision of the ligated tissue between them.

The staple sizes are different in the inner and outer rows. The choice of size is based on the type of operation. For example, vascular or thin load sizes of approximately 2 mm or 2.5 mm are used for vascular applications, while large load sizes of approximately 3.5 mm are used for intestinal applications.

Each staple size has its own cartridge color (e.g. gray for 2 mm staple size, tan color for 2.5 mm, purple for 3.5 mm, and black for 4.5 mm). The staples also have different cutting lengths (30, 45, and 60 mm) which are used according to the length of tissue that will be divided.

Before firing and tissue division, the tissue is atraumatically crushed between the stapler and its opposing anvil. A rotational ability of 360° is present in all staplers with either a straight or articulating head. The articulating head offers a wide range of mobility and angulation before application on the tissue, but articulating staplers are more expensive. Noncutting staplers use fewer rows (three or four) of staples.

### Principles of endoscopic stapler application

Several precautions must be taken into consideration before using a laparoscopic stapling device. These are outlined in Box 82.5 and Figure 82.8.

### Complications of endoscopic stapler

In general, the primary stapler malfunction rate ranges from 0.3% to 0.5% [31–33]. If the jaws do not close easily because there is thick surrounding tissue around the target pedicle, there is an increased risk of incomplete ligation and subsequent bleeding. The complication rate associated with using the Endo GIA to ligate the renal vein has been reported to be between 1% and 1.7% and leads to morbidity in 45% of cases, a conversion rate of 20–27%, and need for transfusion in 15% [32, 33]. However, the majority of Endo GIA complications are likely attributed to poor instrument handling or application of an incorrect stapler width rather than equipment failure. At least 3 cm of the vein must be dissected to reduce the risk of complications and to enable accurate stapler position prior to vein ligation. On the right renal vein this can be difficult to achieve because of its short length. For the left renal vein, care should be taken to avoid any clips used before applying the stapler, because if the clip gets trapped between the stapler's jaws it may lead to Endo GIA malfunction and renal vein division without applying the staples. The subsequent outcome is disastrous.

See accompanying Video 82.1.

**Box 82.5 Basic principles of stapler application during minimally invasive surgery.**

- A 12 mm port size is required to pass it safely into the abdomen. For thick and large 4.8 mm staples a 15 mm port size is needed
- During introduction and withdrawal of the stapler, the jaws should be closed to prevent inadvertent trocar dislodgement
- All staplers are incorporated with a safety mechanism to avoid premature stapler deployment or blade cutting. The safety button must be disengaged prior to firing
- The target tissue must be properly dissected from the surrounding connective tissue to a suitable thickness
- The stapler's arms should to be placed accurately, with both tips visible, and closed easily without undue pressure
- The use of a noncutting stapler (e.g. endoscopic TA device) has been advocated to minimize the risk of stapler misfire. Then, the target pedicle can be divided after vessel ligation
- During firing, any torque of the stapler must be avoided. Serious complications (e.g. incomplete ligation or avulsion of the target vessel) may result
- After firing, open the jaws slowly before withdrawing the stapler. The division line should be inspected to ensure proper hemostasis
- In some instances, additional stapler reload or metallic clip application may be required to complete the vessel ligation
- During a second stapler reload, the inclusion of a previously placed titanium clip into the jaws must be avoided, as this will compromise both staple deployment and cutting mechanism
- Use of clips should be minimized on the target area where a stapler use is anticipated to avoid difficulty in maneuvering the stapler

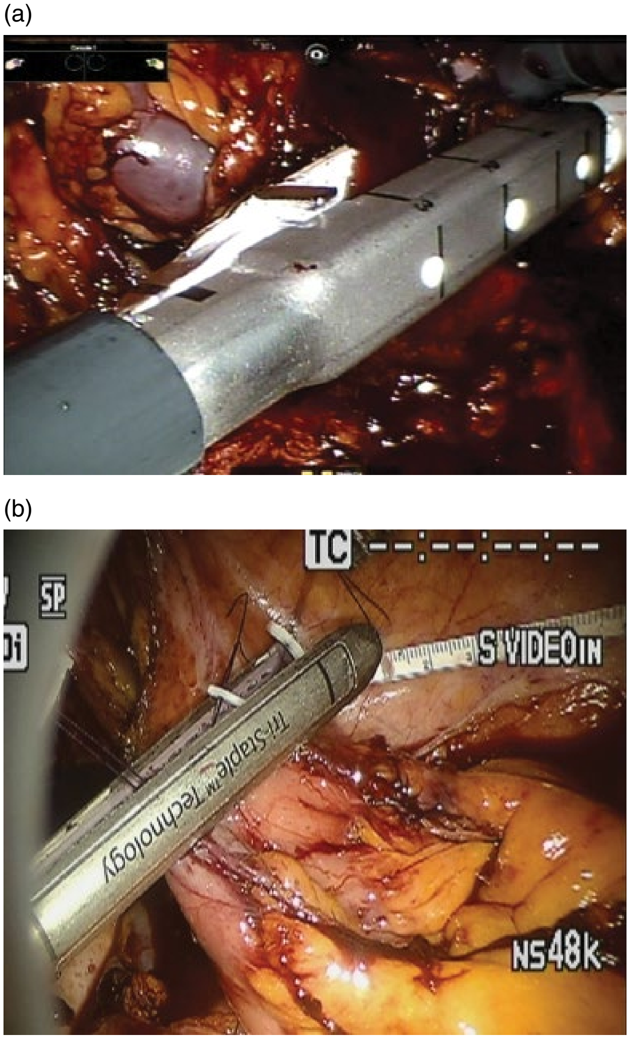

**Figure 82.8** (a) Application of 45 mm–2.5 mm Multifire Endo GIA™, Covidien) stapler device for ligation and division of the renal vein during robot-assisted nephroureterectomy. For ideal and safe vascular division the target tissue must be properly dissected from the renal vein and both tips should be visible before jaw closure, as illustrated. # Transperitoneal Access and Trocar Placement

*Angelo Territo & Alberto Breda*

*Uro-Oncology Division and Kidney Transplant Units, Fundació Puigvert, Autonoma University of Barcelona, Barcelona, Spain*

## Introduction and general considerations

Pure laparoscopy and robotic surgery are minimally invasive approaches to access the abdominal cavity for diagnostic or therapeutic purposes, using dedicated instruments. At present, the transperitoneal approach has become widespread and more popular than the retroperitoneal approach due to the familiar intraperitoneal anatomy and the larger available working space. Any transperitoneal laparoscopic or robotic procedure starts with the establishment of a pneumoperitoneum, followed by trocar placement. The choosing of the optimal site on the abdominal wall is the first step in transperitoneal access. In general, the initial site is used to introduce the video-laparoscope. The number, size, and arrangement of the other trocars depend on the type of procedure, patient's body habitus and surgeon's experience. Furthermore, in choosing the entry site it is mandatory to consider previous surgical scars and anatomic anomalies, in order to avoid the risk of injuries. In this chapter, we describe the current "state of the art" regarding pure laparoscopic and robotic transperitoneal access and trocar placement in the most common urological procedures. Advantages, limits, and complications related to transperitoneal access and trocar placement will also be described.

## Anterior abdominal anatomy

Knowledge of the abdominal wall is fundamental to any open or laparoscopic/robotic procedure. The abdominal skin is backed by Camper's fascia, a loose layer of fatty tissue varying in thickness depending on the patient's nutritional status. In this layer superficial circumflex iliac, external pudendal, and superficial inferior epigastric vessels branch from the femoral vessels. The abdominal wall is composed of five paired muscles: two vertical muscles (rectus abdominis and pyramidalis), and three layered, flat muscles (external abdominal oblique, internal abdominal oblique, and transversus abdominis). These muscles and their fascial attachments form a protective layer that supports the anterolateral abdominal wall (Figure 83.1) [1]. Superior epigastric artery and vein (direct continuations of the internal thoracic vessels) provide blood supply to the superior half of these muscles. The inferior epigastric artery and vein, which arise from the external iliac vessels, approximately 1 cm below the inguinal ligament, supply the inferior portion of the rectus muscles and run superiorly until the anastomosis with the superior epigastric vessels. Furthermore, lower intercostal vessels provide additional vascularization [1] (Figure 83.1). Underneath the muscle layers, the transversalis fascia and the anterior layer of the peritoneum are found before entering the intraperitoneal space (Figure 83.1).

### Access to peritoneal cavity and creation of pneumoperitoneum

The transperitoneal approach requires the establishment of a successful pneumoperitoneum. The first step is to optimize entry technique in order to avoid injuries in the abdominal cavity [2]. Three techniques are described: the Veress needle technique, open (Hasson) technique, and direct optical access. The choice of the best method of transperitoneal access is still debated in terms of safety, and there is insufficient evidence to recommend one entry technique over another, although the open access and the direct visual trocar entry appear to have lower minor complications and faster access when compared to the Veress needle entry [3–5].

## Closed entry technique

A common approach to enter the abdominal cavity and create the pneumoperitoneum is by using a Veress needle. This needle is composed of an inner blunt-tipped obturator and an outer sharp-tipped sheath. This design protects the intra-abdominal structures thanks to the advancement of the inner sheath after the outer sheath encounters an area of decreased resistance (peritoneal cavity). Commonly, access with a Veress needle is obtained in the periumbilical area, and far from previous surgical scars (Figure 83.2a). The needle is inserted, tenting the abdominal wall upward (Figure 83.2a). The rationale for lifting the abdominal wall is to increase the abdominal wall tension against which to push the Veress needle and to increase the distance between the bowel and the major retroperitoneal vessels. The Veress needle is held between the thumb and index finger. In the majority of cases, two clicks can be heard, which correspond to the two areas of

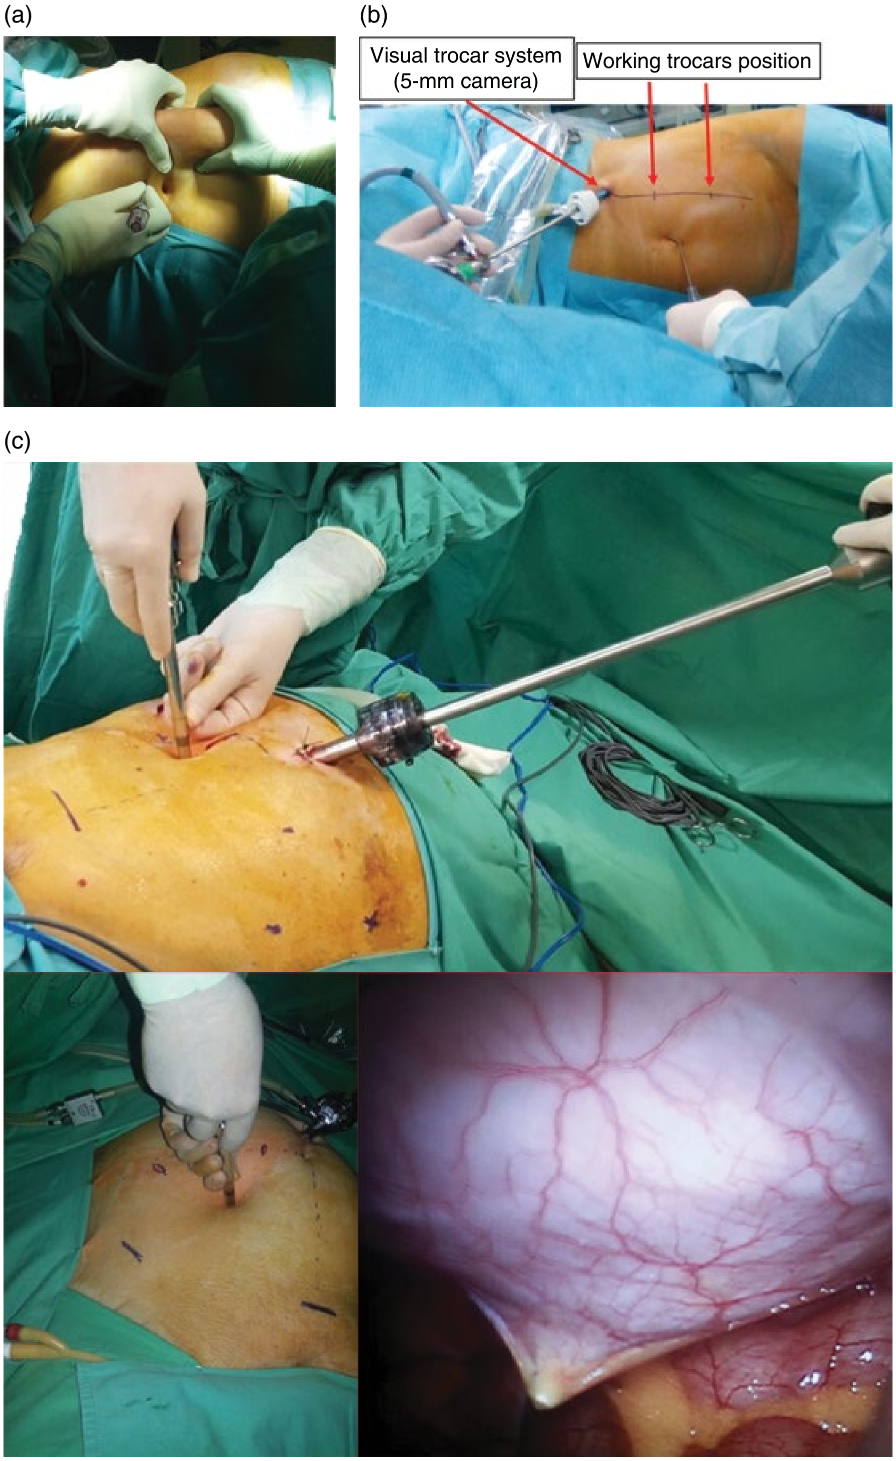

**Figure 83.2** (a) The Veress needle access in periumbilical area, tenting the abdominal wall upward. (b) Initial trocar placement one fingerbreadth inferior to the costal margin, using a visual trocar system with a 5 mm camera and 0° lens (the lens is immediately changed to a 30° one in order to place working trocars and perform the procedure). (c) Second trocar placement at a 90° angle to the abdominal wall and pushed inside until the tip of the trocar can be seen with the laparoscope. *Source:* From Fundaciò Puigvert, Spain.

maximum resistance encountered as the needle passes through the two abdominal wall fascia layers: muscle fascia and peritoneum. Correct placement of the needle into the peritoneal cavity must be quickly verified with the drop test, which consist of injecting 3–5 ml of saline into the Veress needle. In case of correct intraperitoneal placement, the saline is sucked inside the needle due to the negative intraperitoneal pressure. It is also important to aspirate the saline back to verify that no blood, bowel contents, or urine are present. If the first entry attempt fails, a second attempt is performed before choosing an alternative entry site.

An initial gas pressure below 9 mmHg reflects the correct intraperitoneal Veress needle placement [6]. It is important to avoid any movements of the needle after its placement in the abdominal cavity. When the Veress needle is correctly positioned, the insufflation of $CO_2$ gas can start. The initial intra-abdominal insufflation pressure is normally set at 12–15 mmHg, with 3–6 liters of $CO_2$ per minute. Once adequate intraperitoneal pressure is achieved, the first trocar can be placed (Figure 83.2b). Video-endoscopic inspection is performed immediately after to verify the intraperitoneal trocar placement and to check for potential intraperitoneal injuries.

### Open entry technique

The open entry technique was first described by Hasson in 1974 [7] and provides direct access to the peritoneal cavity. A mini-laparotomy (1.5–2 cm) at the umbilical area or pararectal line is usually performed. The fascia is exposed with narrow retractors and incised. The peritoneum is identified by sharp dissection of the muscles, tented up, and incised under vision. At this point, the peritoneal cavity adjacent to the incision should be explored with a finger to ensure absence of adhesions. The Hasson trocar is placed immediately after and pneumoperitoneum is initiated. This port consists of a blunt trocar, a cannula with an adjustable conical sleeve, and suture-holding arms for fixation.

### Direct optical access

The direct optical access is an alternative to the Veress needle. Optical trocar access is considered by many the safest entry method and is associated with a low incidence of intraoperative complications [8]. Nevertheless, in the obese population a randomized controlled trial showed that the Veress needle insertion technique is safer than direct trocar insertion using a nonoptical bladed trocar [9].

A 5 or 10 mm laparoscope is placed directly into the visual trocar sheath. The trocar is then pushed with a twisting motion stepwise into the peritoneal cavity, visualizing each abdominal wall layer during the trocar movement. Under the continuous gentle rotation of the optic trocar, the sequential layers of subcutaneous fat, anterior rectus sheath, pre-peritoneal fat, and peritoneum are visualized [10]. Once inside, the $CO_2$ is connected and pneumoperitoneum is obtained.

## Principles of trocar placement

The camera and working trocar arrangements depend on the type of surgical procedure and the surgeon's individual preference or experience. Commonly, triangulation is considered a basic principle of laparoscopic port placement, and for this reason the trocar arrangement is described as using a four-point diamond configuration, in which the operative site is enclosed within the diamond, with the camera placed between two working trocars [11]. For upper tract transperitoneal surgery, the camera is often placed in the periumbilical area with the other trocars positioned according to the exact procedure, the location of the disease, and the body habitus of the patient [12]. For renal and adrenal laparoscopic surgery performed in obese patients, port placement is further modified by shifting it laterally. Once the aiming point has been located, second trocars are placed at a 90° angle to the abdominal wall and pushed inside until the tip of the trocar can be visualized with the laparoscope, in order to avoid intraperitoneal injuries (Figure 83.2c).

Laparoscopic transperitoneal reconstructive surgery in which laparoscopic suturing is needed still represents a challenge, mostly due to spatial limitation, fixed trocar positions, and restricted instrument movements. In order to optimize laparoscopic suturing, Frede et al. [13] found that an isosceles triangle trocar arrangement is needed, and the angle between laparoscopic instruments should be adjusted to between 25° and 45°. Even if this positioning is intuitive and replicates human anatomy with an arm on either side of the point of view, this arrangement often fails to be ergonomic, due to interactions between the assistant holding the camera and the surgeon.

In order to reduce this arm conflict between the surgeon and camera holder, and obtain a better ergonomic working position for both, Harper et al. [14] were the first to describe a linear port configuration suitable for all urological transperitoneal laparoscopic renal and adrenal surgery. After creating the pneumoperitoneum with a Veress needle, the first and uppermost port is placed one fingerbreadth below the costal margin, using a visual trocar. The camera is introduced through this trocar. The middle (second trocar) and inferior trocars (third trocar) are placed approximately four fingerbreadths apart. The lowest inferior trocar is approximately at the level of the umbilicus, rarely lower. A fourth port is often placed off the tip of the 11th or 12th rib and used for retraction (Figure 83.3).

For right-sided cases, the first trocar is placed two fingerbreadths lower than the left side (because of the liver) and a trocar for liver retraction is also placed in the midline, right below the xiphoid sternum. Considering this trocar arrangement, both working ports are to one side of the camera and the surgeon's point of view remains intuitive.

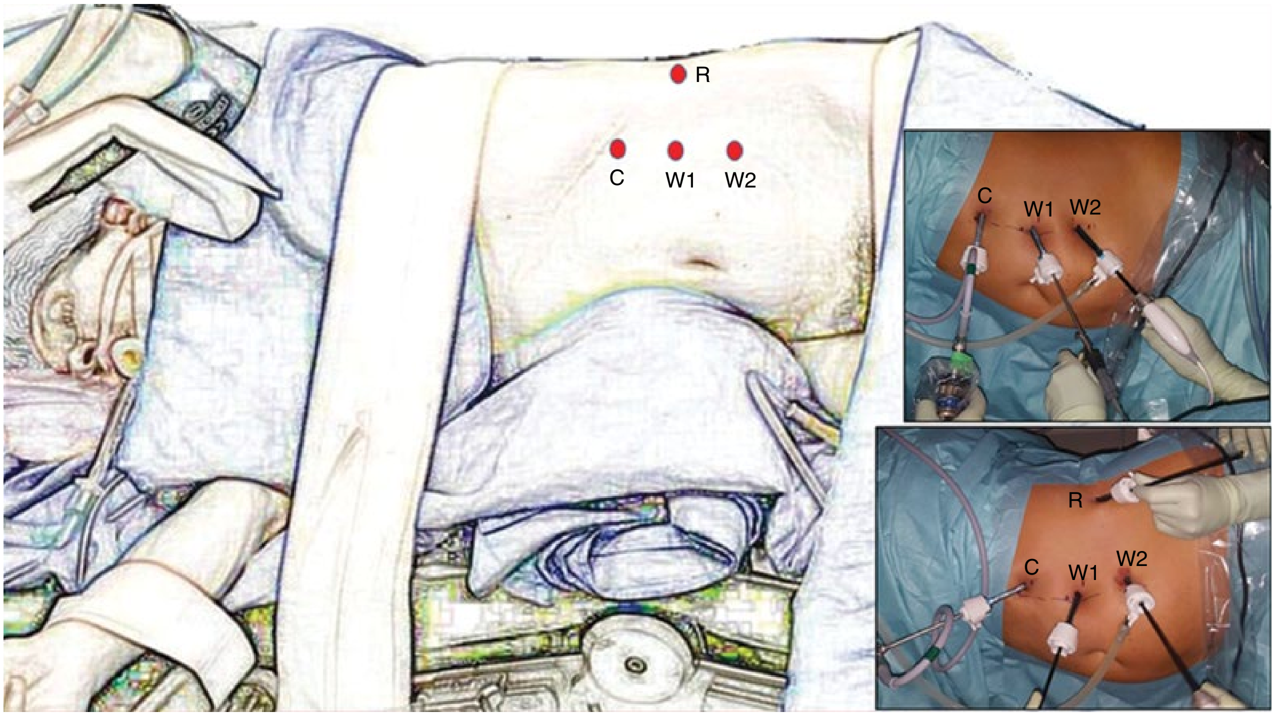

**Figure 83.3** Linear port configuration for left side upper tract surgery using three 5 mm trocars along left pararectal line and a fourth 5 mm port placed off the tip of the 11th or 12th rib for retraction. C, camera; W1 and W2, working ports; R, retractor). *Source:* From Fundaciò Puigvert, Spain.

Furthermore, the authors [14] described the use of a 30° lens that is usually oriented in line with the surgeon's angle of view. Linear port placement along the pararectal line is well suited also in cases of performing sutures (pyeloplasties and partial nephrectomy renorrhaphy), positioning the camera temporarily through the middle trocar. This generates a helpful separation of the laparoscopic instruments, making suturing and knot tying quicker and easier [14].

### Choice of the trocar and laparoendoscopic single-site surgery

The choice of trocar size depends on the instruments needed for the procedure. Generally, in laparoscopic surgery, trocars from 3 to 12 mm can be used. When larger instruments such as entrapment devices or endoscopic ultrasound probes are needed [14], larger trocars are available as big as 15 mm. Trocar length is usually the standard 10 cm, although longer trocars (15 cm) are available for obese patients.

Recently, in a multicenter prospective study, Breda et al. [15] evaluated the role of mini-laparoscopy, using 3 mm instruments and a laparoscope, in renal and adrenal surgery. The same mini-laparoscopic approach was also proposed in live donor nephrectomy as an attractive alternative to the standard laparoscopy [16]. The authors found that the operative time was possibly longer than that in a standard laparoscopy, but clinical and safety outcomes were not compromised. Furthermore, mini-laparoscopy provided excellent pain control and cosmetic results by minimizing the incision site [15].

As far as the type of trocar to use is concerned, many are available, including bladed, bladeless/blunt, and radially dilating trocars. According to the literature, bladeless/blunt and radially dilating trocars are preferred to the bladed ones due to a lower incidence of bleeding, hernia, and pain. Furthermore, by using radially dilating devices, fascial closure can be avoided [17–20].

Finally, laparoendoscopic single-site (LESS) surgery was introduced in urology in order to decrease morbidity and improve recovery times and cosmetic results [21]. The umbilicus is the most frequently used access site, with a 4–5 cm periumbilical incision. There are multiple LESS devices available, the majority of which include a multichannel port [22].

## Complications related to trocar placement and transperitoneal access

### Trocar-related complications

Trocar-related complications such as trocar site bleeding, herniation, infection, and postoperative pain may be related to the type and size of trocars [17]. Abdominal wall vessel injury (usually the epigastric vessels) can be managed with direct coagulation through a second trocar placement. If direct coagulation fails, a Carter–Thomason closure device may provide a figure-of-eight absorbable suture in order to control the bleeding. The risk of hernia occurrence in the entry site increases with the trocar size used, although fascial closure is performed [23]. The data reported by Kadar et al. showed an increasing port site hernia rate of 3.1% using 12 mm trocars compared with 5/10 mm ports. The same authors also recommended closure of the fascia after laparoscopic procedures using larger than 5 mm trocars [24]. The majority of these hernias occurred within the first two weeks, with a range between a few hours and 1 year [25] and the most frequent site of occurrence is the umbilical scar [23]. Shalhav et al. [26] found that by using blunt trocars rather than sharp trocars the risk of hernia formation could be limited due to the mechanism of insertion. A blunt trocar penetrates the abdominal wall layers by splitting fibers, allowing a nontraumatic separation of the tissues and a spontaneous muscle reapproximation after trocar removal.

Although infrequent, port site infection is one of the most bothersome complications in laparoscopic and robotic surgery, increasing patient morbidity. Infections are more common at the umbilical port [27]. In this site, the infection may be related to the specimen extraction technique. For this reason, Sasmal et al. underlined the importance of irrigating and cleaning the port site before closure and removing the specimen in an endobag [27]. Furthermore, the risk of port site infections increases in cases of diabetes, malnutrition, a history of nicotine or steroid use, a long pre- and postoperative hospital stay, and blood transfusion [28].

Postoperative pain has been consistently evaluated. Cristaudi et al. [29] reported on postoperative pain and cosmetic results using 5 mm and larger trocars. Pain assessment was measured with visual analog scale. The authors reported significantly lower pain using 5 mm trocars compared to the larger sizes, in particular in the lower abdomen, and the scar assessment score was significantly lower for the 5 mm trocar. Breda et al. also reported excellent pain control and cosmetic results using 3 mm trocars [15].

### Intra-abdominal complications

Complications related to transperitoneal access include intra-abdominal vascular and visceral injuries. During the creation of the pneumoperitoneum, the most common major vascular injuries are at the level of aorta and inferior vena cava [30]; although rare, these lesions may require a fast open conversion to control bleeding. Two multicenter studies found that the risk of vascular injury is higher in the direct trocar insertion technique than in the open technique [31,32]. Spleen, liver, and bowel injuries are mainly related to blind initial access, either through a trocar or Veress needle [33]. The choice of an entry point away from an abdominal scar (previous surgery) and insufflation at or above the midclavicular line when in the flank position can avoid these injuries.

Although liver injuries rarely represent a problem, splenic injuries frequently require revision, which sometimes ends up with a splenectomy. A bowel injury can be suspected with aspiration of intestinal fluid or in case of irregular abdominal insufflation. Any bowel injury, including serosal abrasions, should be treated at the time of recognition. In case of a small and isolated injury, the area of injury can often be repaired with laparoscopic suturing. Larger injuries may require laparotomy [34]. In the case of a misdiagnosed intraoperative bowel injury, postoperative presenting symptoms may include leukopenia or diarrhea, abdominal pain, or fever. Diagnosis can be confirmed by a computed tomography (CT) scan [35].

## Trocar placement in laparoscopic and robotic transperitoneal procedures

### Adrenalectomy

Using a laparoscopic or robotic technique, several surgical approaches have been proposed, including the anterior and lateral transperitoneal and retroperitoneal, the last being first described by Mercan et al. in 1995 [36]. Although there is no consensus on optimal access, the most commonly preferred approach to the adrenal gland is transperitoneal, since it provides a larger operative field, wider visibility, and more anatomical familiarity for urologists [37–39]. With the patient in a lateral decubitus, the procedure is usually performed using 3–4 ports. The size of the ports depends on the surgeon's preference although a 10/12 and two to three 5 mm trocars are usually the most commonly adopted. The trocars are usually placed in a circular configuration, with the camera port placed in the periumbilical region. The working trocars are arranged in the anterior axillary and midaxillary line, and an additional retractor placed lateral to the working trocars [40]. A different configuration is also described for laparoscopic adrenal surgery, consisting of ports arranged along the ipsilateral costal margin [12, 41] (Figure 83.4a,b). Linear trocar placement along the pararectal line (Figure 83.3) with all 5 mm trocars is also possible for both right and left laparoscopies, only shifting the inferior port laterally in a right-sided adrenalectomy

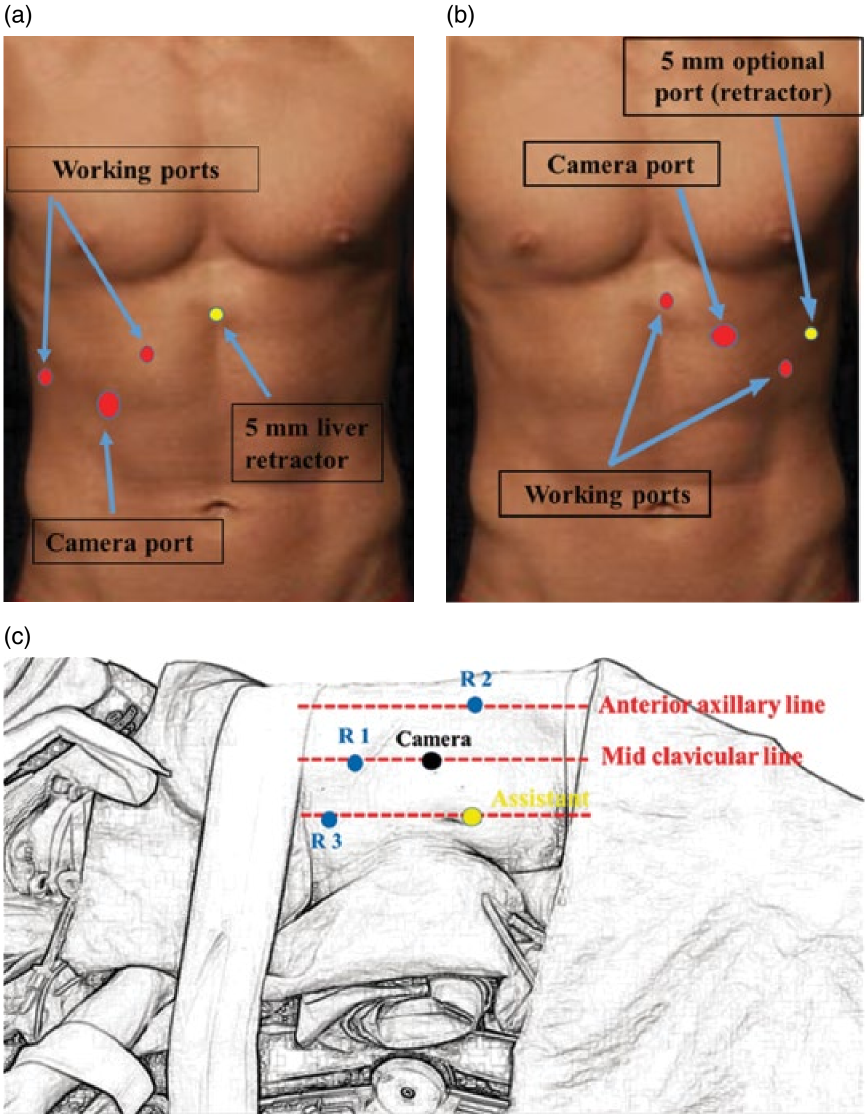

**Figure 83.4** Port placement for transperitoneal laparoscopic adrenalectomy along the costal margin in right side (a) and left side (b). Left robotic adrenalectomy trocar placement (c) using four-armed da Vinci System: one 12 mm camera port, one 12 mm assistant port, and the three 8 mm robotic arm ports (R1, R2, and R3). to facilitate the dissection at the inferior vena cava and adrenal vein junction [14]. The robotic trocars arrangement is shown in Figure 83.4c.

## Live donor nephrectomy

The choice of the kidney for live donation remains a dilemma since a right-sided donor nephrectomy is associated with a shorter renal vein (more technically challenging for the anastomosis) [42]. Therefore, laparoscopic left live donor nephrectomy is often performed. The patient is placed in a flank position. The pubic area is included in the field to facilitate suprapubic incision (Pfannenstiel incision) and kidney extraction. The pneumoperitoneum is created [43, 44]. A classical triangular diamond-shaped configuration with the camera port in the middle is traditionally used. In this configuration a 10/12 mm trocar is usually placed lateral to the umbilicus along the pararectal line (alternatively the camera can be inserted at the umbilicus, although we believe this position to be uncomfortable) and two working ports (5 and 12 mm) are inserted at four or five fingerbreadths from the camera bilaterally in a triangular shape configuration (Figure 83.5a). An additional 5 mm trocar can be inserted at the tip of the 11th or 12th rib for lateral retraction.

In our own practice, we usually create the pneumoperitoneum using a Veress needle [14]. We use all 5 mm laparoscopic instruments as well as a linear trocar

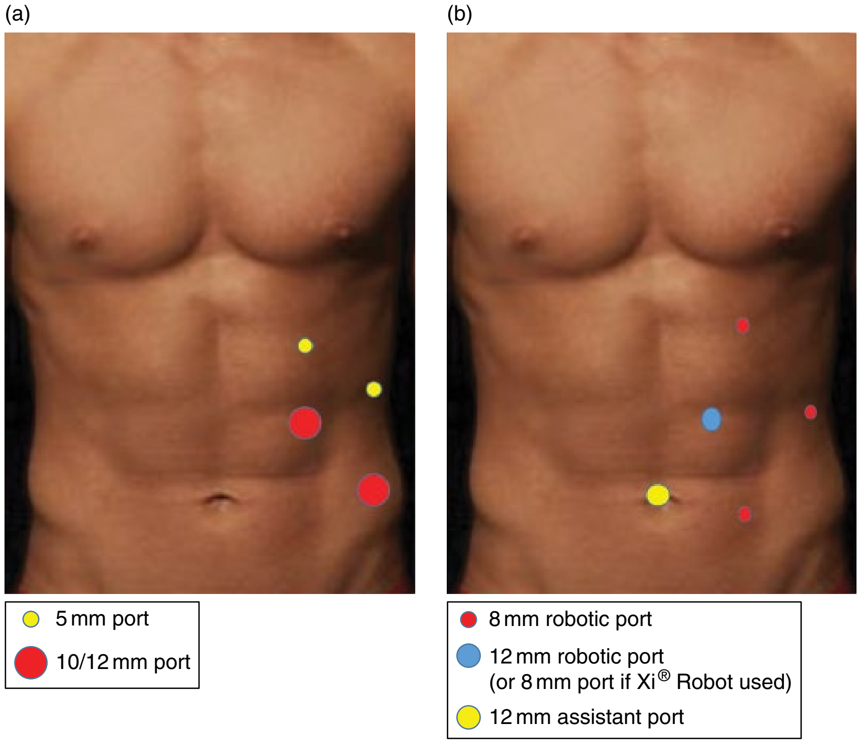

**Figure 83.5** Port placement in laparoscopic (a) and robotic (b) live donor nephrectomy, nephroureterectomy, radical, and partial nephrectomy. *Source:* From Fundaciò Puigvert, Spain.

configuration along the ipsilateral pararectal line, with the camera placed at the most cephalic position. The middle (5 mm second trocar) and inferior trocars (5 mm third trocar) are placed approximately four fingerbreadths apart. A fourth trocar off the tip of the 11th or 12th rib is added as a retractor (Figure 83.6a,b). A Pfannenstiel-like incision is made approximately at the pubic hairline, through which a 15 mm trocar is inserted. Through this port the endovascular stapler may be introduced, as well as the placement of the 15 mm Endo Catch™ bag for kidney extraction (Figure 83.6c). Alternatively, a hand-assisted device can be inserted at the umbilicus for faster kidney extraction [14].

Considering a robotic approach, the patient is positioned in a 45° dorsal position and a 10/12 mm trocar is placed at 3 or 4 cm lateral to it at the pararectal line. Under direct endoscopic vision, two or three robotic ports (8 mm) are placed, as in laparoscopic nephrectomy, with one assistant (10/12 mm) trocar at the level of the umbilicus (Figure 83.5b) [45,46].

## Radical and partial nephrectomy

The patient is positioned in lateral decubitus in both the robotic and laparoscopic approaches. Laparoscopic trocar disposition using a classical triangular configuration was recently reported by Gaunay et al. [47] and is shown in Figure 83.5a. On the right side, an additional trocar can be used for liver retraction, positioned in the epigastrium, just inferior to the xiphoidal process. In obese patients it is recommended to shift this configuration laterally to the rectus muscle in order to reduce the distance from the target tissue [47]. Linear port configuration along the ipsilateral pararectal line is also available for both laparoscopic radical and partial nephrectomy, with the camera placed at the most cephalic position port as described above. When performing a suture, as in a partial nephrectomy, the camera is temporarily placed in the middle trocar, making knot tying quicker and easier [14].

Using a robotic approach for radical and partial nephrectomy, two types of trocar configurations can be used: medial (Figure 83.5b) [48] and lateral [49] camera port placement. In the medial camera port configuration, a 10/12 mm camera port is placed in the periumbilical area using a 0° or 30° angle-down scope with the patient in a full or modified flank patient position, similar to the pure laparoscopic approach. An 8 mm subcostal robotic trocar is positioned in the anterior axillary line. Another 8 mm robotic trocar is situated in the posterior axillary line, about 2 cm above the iliac crest. A 12 mm assistant trocar is placed in the low midline in order to allow the passage of bulldog clamps, sutures, and suction. An additional 12 mm subxiphoid assistant trocar can be positioned for the retraction and the passage of bulldog

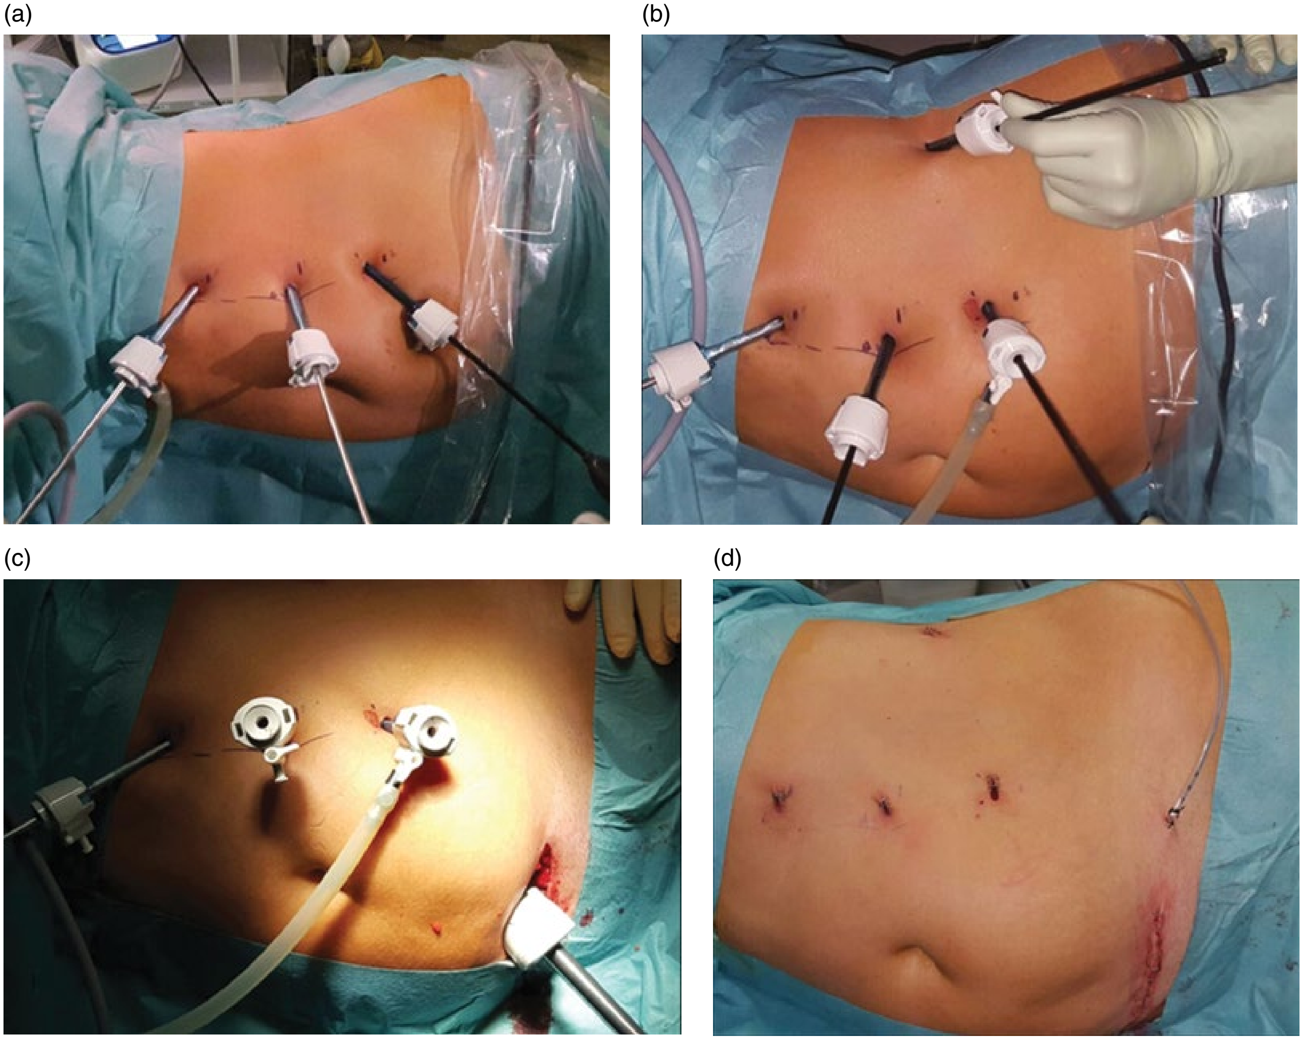

**Figure 83.6** Laparoscopic left live donor nephrectomy. (a) Linear port configuration along the pararectal line (camera holder at the most cephalic position). (b) An additional trocar used as retractor. (c) Through a Pfannenstiel incision a 15 mm trocar is placed to introduce endovascular stapler and the 15 mm Endo Catch bag for kidney extraction. (d) Final view of trocar positions and Pfannenstiel incision. *Source:* From Fundaciò Puigvert, Spain.

clamps from a different angle. The lateral camera port configuration uses a 30° angle-up laparoscope with the patient in the full flank position. In this kind of lateral configuration, a 12 mm camera port is placed a hand's width from the costal margin, between the midclavicular and anterior axillary line. The lateral camera port assessment avoids conflict between working arms and allows hilum dissection without needing help from an assistant for bowel retraction. If the new Xi machine is used a forth arm can be used for lateral retraction.

### Nephroureterectomy with bladder cuff excision

The modified lateral decubitus position is used in both laparoscopic and robotic approaches. Trocar assessment for laparoscopic nephroureterectomy is identical to the trocar configuration used for laparoscopic radical nephrectomy, using an additional 12 mm port suprapubic (in the midline between the umbilicus and the pubis) to perform distal ureter dissection and bladder cuff excision [47]. As in radical and partial nephrectomy, this configuration is shifted laterally in obese patients. Trocar assessment in robot-assisted nephroureterectomy was recently reported by Gaunay et al. [47] (Figure 83.5b). The issue regarding the best method for distal ureter dissection and bladder cuff excision remains controversial and is largely based on surgeon preference for both laparoscopic and robotic approaches [50]. However, the open approach is considered the safest, using the same single incision for specimen extraction and bladder cuff excision [51] and it is the approach that we recommend.

## Ureteral procedures

Several ureteral procedures, including pyeloplasty, ureterolithotomy, and ureterovesical reimplantation, are treated using conventional laparoscopy or a robot-assisted approach [52,53]. Depending on the ureteral tract to be treated, different trocar configurations, using three or four trocars, are possible. A linear port configuration (Figure 83.3) and trigonal or rhomboidal arrangements (Figure 83.7a) can be used for laparoscopic upper tract ureteral procedures. The trocar assessment for a robotic approach is allocated in a V-shape fashion (Figure 83.7b). In the case of low ureteral procedures, the patient is positioned in a supine fashion for both pure laparoscopy and robot-assisted surgery and trocar configuration is as shown in Figure 83.7c. For both laparoscopic and robotic approaches, one periumbilical trocar is placed for the camera (5–10 mm). Furthermore, two ports are placed, at two or three fingerbreadths medially to the anterior superior iliac crest bilaterally. An additional assistant trocar can be inserted in the suprapubic space to provide further help [52,53].

## Bladder surgery and pelvic lymph node dissection

Both laparoscopic [54] and robotic [55] approaches for radical cystectomy were introduced in order to decrease morbidity rate and length of hospitalization. Although many trocar positions have been described [55,56], our recommendation for laparoscopic radical cystectomy and pelvic lymphadenectomy is a five-port configuration (Figure 83.8a). A 10/12 mm trocar is positioned 1–2 cm above the umbilicus. A second 10/12 mm trocar is introduced at 8 cm in a virtual line between the umbilicus and the left iliac crest, followed by a 5 mm trocar at two fingerbreadths from the right iliac crest. Furthermore two additional assistant 5 mm trocars are placed in a similar linear fashion separated 8 cm from each other on the right.

The same port configuration is adopted in the robotic procedure with extracorporeal neobladder reconstruction or ileal conduit, with the addition of a 5 mm trocar for the assistant as shown in Figure 83.8b (with the 8 mm robotic trocars). Collins et al. [57] described radical cystectomy with intracorporeal neobladder diversion using a robotic approach. In this case, the camera port is placed 5 cm above the umbilicus. Two 8 mm robotic ports are placed bilaterally at umbilicus level, lateral to the rectus sheath. A 15 mm trocar is positioned just above and medial to the left superior iliac spine, allowing the use of laparoscopic stapling when the robotic arm is temporarily disconnected. Two 12 mm assistant ports are placed on the right side (Figure 83.8c) [57]. Laparoscopic and robotic trocar assessment for other bladder procedures, including partial cystectomy, diverticulectomy, and augmentation cystoplasty, do not vary from the previous described position for radical cystectomy.

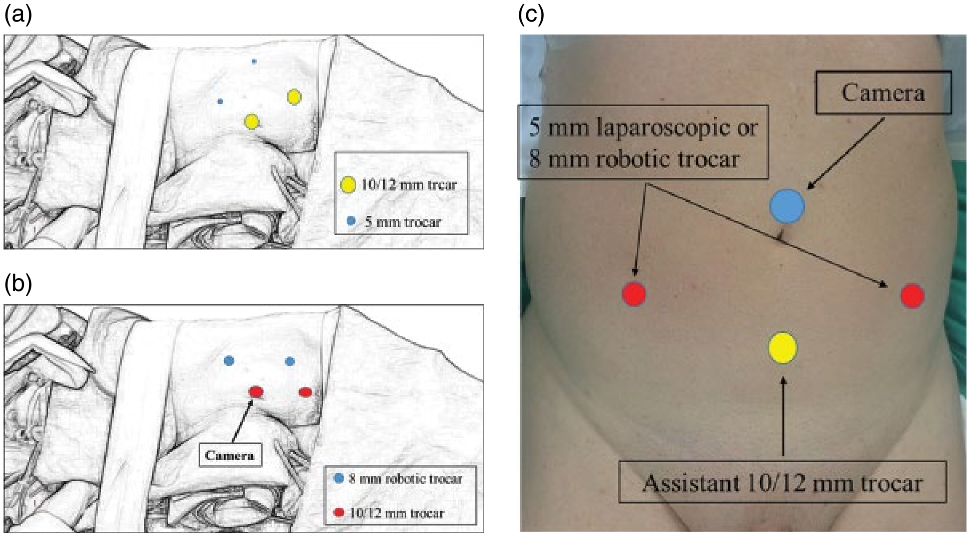

**Figure 83.7** (a) Port placement in laparoscopic upper tract ureteral procedures: 10 mm umbilical trocar, a 5 mm trocar under the edge of the costal arch, and a 12 mm trocar between the umbilicus and pubis. (b) Port placement in robotic upper tract ureteral procedures: two 8 mm trocars (the inferior trocar at 3 cm above the anterior superior iliac spine), a 10–12 mm umbilical trocar (camera), an additional 10–12 mm assistant trocar between the umbilicus and the pubis to provide quicker suture exchange. (c) Laparoscopic and robotic port placement for lower tract ureteral procedures: two ports at 2 cm medially to the anterior superior iliac spine and an additional 10–12 mm assistant trocar in the suprapubic space. *Source:* From Fundaciò Puigvert, Spain.

## Radical prostatectomy

In both laparoscopic and robotic approaches a 10/12 mm port is positioned about 2 cm above the umbilicus for camera introduction. Furthermore, it is important to underline that the laparoscopic and robotic trocar arrangement may vary depending on height, weight, previous surgical scars, and pelvis anatomy. The trocar placement in laparoscopic radical prostatectomy is shown in Figure 83.9a. A 5 mm trocar is inserted four fingerbreadths lateral to the umbilicus in the anterior axillary line on the right side. Another 5 mm trocar is positioned at distance of three or four fingerbreadths from the other in the direction of the anterior iliac crest. On the left side, a 12 mm trocar is placed lateral to umbilicus at 8–9 cm in the anterior axillary line, and a further 5 mm trocar is placed symmetrical to the contralateral one.

Several port positions have been reported for robotic radical prostatectomy, with the optical trocar at the level of or just above the umbilicus [58–60]. The trocar placement in robotic radical prostatectomy is shown in Figure 83.9b. An 8 mm robotic trocar is placed at 10 cm from the umbilicus, both on the right and on the left side along the anterior axillary line at 15–18 cm from the pubic bone. Alternatively, these two trocars can be positioned at 8–10 cm bilaterally

in a virtual line between the camera and the superior iliac crest. On the left side, an 8 mm robotic trocar is placed at two fingerbreadths from the iliac crest for the fourth arm. An assistant 5 mm trocar is placed three fingerbreadths on the right side parallel to the umbilicus; a second assistant 12 mm trocar is placed three fingerbreadths from the superior anterior right iliac crest. In cases of a small pelvis, the robotic port configuration can be modified, positioning the most lateral ports on the left side more horizontally, 7 cm apart from the other robotic trocars.

## Conclusions

Although there is no strong evidence from the literature, it appears that the induction of pneumoperitoneum is safer when open access or direct optical access are performed.

Minimizing the trocar size reduces complications and postoperative pain, as well as giving better cosmetic results. Bladeless and radially dilating trocars should be used rather than bladed ports to minimize bleeding and postoperative port site hernias.

Traditionally, in renal and adrenal surgery, laparoscopic port placement relies on a diamond triangular trocar configuration in which the camera is included within the diamond. The linear port configuration has been introduced to standardize and simplify trocar placement for all adrenal, renal, and ureteral procedures.

For pelvic procedures, the optical trocar is maintained at the level of, or just above the umbilicus, with trocar position varying minimally among different procedures.

## Introduction

The first technical part of any urologic laparoscopic or robotic procedure involves obtaining access to either the peritoneum (see Chapter 83) or the retroperitoneal/extraperitoneal space. Access and trocar placement is of critical importance for all minimally invasive abdominal surgery. However, due to the limited working space in retroperitoneoscopic and extraperitoneoscopic surgery, not optimizing access points in these spaces may limit the ability of the surgeon to accomplish the case safely and efficiently. In this chapter we outline the necessary steps for proper patient positioning, primary retroperitoneal access, development of the retroperitoneal space, and secondary trocar placement for both retroperitoneal renal and adrenal surgery as well as pelvic extraperitoneal surgery. In addition, we outline potential inclusion and exclusion criteria to help surgeons select cases ideal for a retroperitoneoscopic renal/adrenal surgery and extraperitoneal laparoscopic and robotic pelvic surgery. Finally, we briefly summarize critical issues related to specimen retrieval and laparoscopic exit at the end of these retroperitoneal and extraperitoneal pelvic access cases.

## Retroperitoneal renal/adrenal access

### Patient evaluation and selection

As with the selection of open surgical approaches, patient characteristics, pathology, and surgeon preference will guide the incision to optimize access for the operation with the goals of avoiding challenging anatomy or scar tissue, improving ease of access to the pathology being addressed, and increasing safety to the patient. Retroperitoneoscopic access to the kidney and adrenal gland mimics a retroperitoneal open flank approach, which can offer several potential advantages over the transperitoneal approach.

Although prior abdominal surgery is not a contraindication to a transperitoneal laparoscopic approach, the number and extent of prior abdominal procedures may render patients more suitable for a retroperitoneal approach to renal or adrenal surgery [1]. Patients with history of peritonitis often have diffuse intra-abdominal adhesions and may benefit from avoiding the peritoneal space. Similarly, patients with abdominal wall or umbilical hernias are at heightened risk of potential bowel injuries when approached via a transperitoneal approach, because bowel and other organs may be contained within the hernia sac. Moreover, abdominal wall reconstruction for complex hernias with mesh can often lead to the development of significant adhesions under the abdominal wall, which can make port placement difficult and limit the working space in a transperitoneal case.

The target organ and the specific site of pathology can also help the surgeon to select a surgical approach. Anatomically, adrenal masses, posteriorly based renal masses, and ureteropelvic junction obstructions can be easily accessed via the retroperitoneoscopic approach and may obviate the need for full renal mobilization, which is often required when addressed via a transperitoneal surgical approach. A retroperitoneoscopic approach can also allow for prompt identification of major vasculature, specifically the renal hilum and the great vessels, circumventing the need for bowel mobilization. Furthermore, approaching the hilum posteriorly can offer direct access to the renal artery, which can allow for expeditious identification and control of the

Companion website: www.wiley.com/go/smith/textbookofendourology

arterial supply for either ligation in cases of radical nephrectomy or clamping for partial nephrectomy.

No definitive exclusion criteria exist for retroperitoneal access, although a few cases may present more challenges for retroperitoneoscopic surgery. Cases of dense retroperitoneal inflammatory fibrosis or any prior retroperitoneal surgery should be evaluated on a case-by-base basis to weigh the risks of transperitoneal versus retroperitoneal access, taking into account the surgeon's preference and comfort level [2]. Prior retroperitoneal access for previous renal surgery, including percutaneous stone surgery or tumor ablation, can lead to scarring within the retroperitoneal fat, resulting in the adherence of natural tissue planes and difficulty in developing the retroperitoneal space. Another relative exclusion is management of large renal/adrenal masses or large-volume hydronephrosis, as the working space in the retroperitoneum is limited; in such cases, a transperitoneal laparoscopic approach would afford the surgeon a more generous working space to approach these problems [3].

## Patient positioning

After induction of general endotracheal anesthesia and sterile insertion of a Foley catheter, the patient is repositioned into a full flank position, similar to the approach for an open flank incision. All pressure points are well padded with surgical towels and/or foam padding to prevent a pressure injury or neuropraxia. Securing the patient in this way allows the table to be rotated from right to left intraoperatively. Some centers use a bean bag under the patient for positioning in the flank position, but in our experience, these devices are not necessary if the patient is well-supported posteriorly with a gel roll or blankets.

The table is flexed at the waist level to open the space between the costal margin and the iliac crest. At this point an axillary roll is placed to help prevent compressive nerve plexus injury. Pillows are placed between the legs and lower extremity pressure points are properly padded. The upper extremities are secured, the dependent arm is placed on an armboard outstretched and the upper arm is placed either in an elevated armboard or secured on pillows. Both upper extremities are maintained in a well-padded, neutral position secured away from the surgical field. The patient is secured to the table with 3-inch tape at the level of the chest and at the hips, taking care not to restrict chest wall movement, which could impair the ability of the anesthesia team to adequately ventilate the patient. The exposed flank and abdomen are prepped and draped in preparation for initiating operative access.

The tip of the 12th rib should be identified; we recommended marking this site prior to prepping the abdomen/flank as palpation of the 12th rib can be impaired after preparation and gloving, especially in the obese patient. After sterile preparation and draping, a line is extended from the iliac crest in a cephalad direction, in the midaxillary line intersecting with the marking of the tip of the 12th rib.

## Placement of initial trocar retroperitoneal access

In the midaxillary line, a 15 mm skin incision is made between the tip of the 12th rib and the iliac crest,. Adjustment of the cranial–caudal positioning of this access trocar is dependent upon the pathology prompting surgery, as well as the use of accessory trocars and the use of the da Vinci robotic system (Intuitive Surgical, Sunnyvale, CA, USA). The incision is carried down to the level of the external oblique fascia. A 10–15 mm incision is made in the fascia with Bovie electrocautery. Fine retractors or blunt finger dissection can be used to spread the abdominal wall musculature down to the lumbodorsal fascia. The lumbodorsal fascia is incised with cautery to open a 1 cm access point. The surgeon's index finger is the inserted into the retroperitoneal space and the tip of the finger should be aimed posteriorly, with the goal of palpating the anterior surface of the psoas muscle (Figure 84.1a). Finger dissection along the surface of the psoas muscle, extending cranially and caudally, will develop the avascular space in the retroperitoneum posterior to Gerota's fascia. The lower pole kidney can typically be felt just anterior to the space developed along the psoas muscle.

Once this space is initially developed, a balloon dilating system can be used to further develop this space prior to port placement. Balloon dissection of the potential space posterior to the kidney was first described for retroperitoneoscopy by Gaur et al. in 1993 [4]. The balloon tip of this visual obturator trocar is inserted just posterior to the kidney anterior to the psoas muscle, in the space previously developed bluntly by the surgeon's finger. The balloon is inflated 20 times (~400 ml) under direct visualization using a 0° or 30° lens 10 mm laparoscope, ensuring that the balloon unfolds and expands in a cranial–caudal orientation. A laparoscope inserted into the device allows for appreciation of the adjacent anatomy through the dissecting balloon as the space is developed. The psoas muscle can typically be assessed posteriorly and the kidney and peritoneum which lay anteriorly. Up to an additional 400 ml is insufflated into the balloon (800 ml in total) (Figure 84.1b). The balloon dissecting trocar is deflated and a balloon working trocar typically used for Hasson entry is placed in the same access site for cases of multiport retroperitoneoscopy. Pneumoretroperitoneum is achieved at a pressure of 15 mmHg through this working trocar.

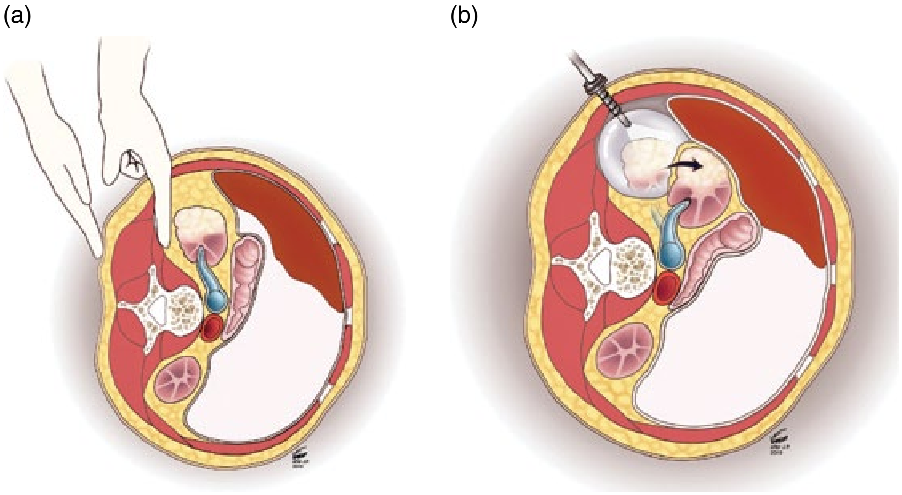

**Figure 84.1** (a) Surgeon's index finger inserted through the lumbodorsal fascia into the retroperitoneal space anterior to the psoas muscle. (b) Balloon dissection of the retroperitoneum. The round-shaped balloon is posterior to the kidney and adrenal gland during pneumodissection. *Source:* Urologybook.com. Reproduced with permission of Urologybook.com.

In cases of laparoendoscopic single-site surgery approached via a retroperitoneal access, the primary access site is developed in a similar fashion with blunt finger dissection, followed by balloon distension of the retroperitoneal space. At this point, the original midaxillary line incision is extended to create a 3–5 cm opening through the skin, abdominal musclulature, and fascial layers to accommodate a multiport single-site access device [5, 6].

## Placement of secondary trocars for retroperitoneoscopic surgery

For cases of conventional multiport retroperitoneoscopic surgery, the primary access trocar is used as a port for laparoscopic visualization during accessory trocar insertion.

The anterior trocar is placed approximately 7–8 cm anterior to the camera trocar site in a line drawn in a cephalad direction from the anterior superior iliac spine. The posterior trocar is placed in a line drawn at the level of the extensor muscles of the back, also at the level of the camera trocar (Figure 84.2). Both accessory trocars are placed under direct laparoscopic visualization.

For the anterior trocar, care is taken to ensure the peritoneum is well shifted anteriorly and the entry space allows direct retroperitoneal access. In some cases, placement of the posterior accessory trocar first will allow for additional peritoneal dissection and mobilization through this posterior working port with a blunt grasping device or laparoscopic Kitner to develop the entry space for the anterior trocar. The posterior trocar may be angled in a slightly more cephalad direction or in some cases the entry may be shifted cranially 1–2 cm,

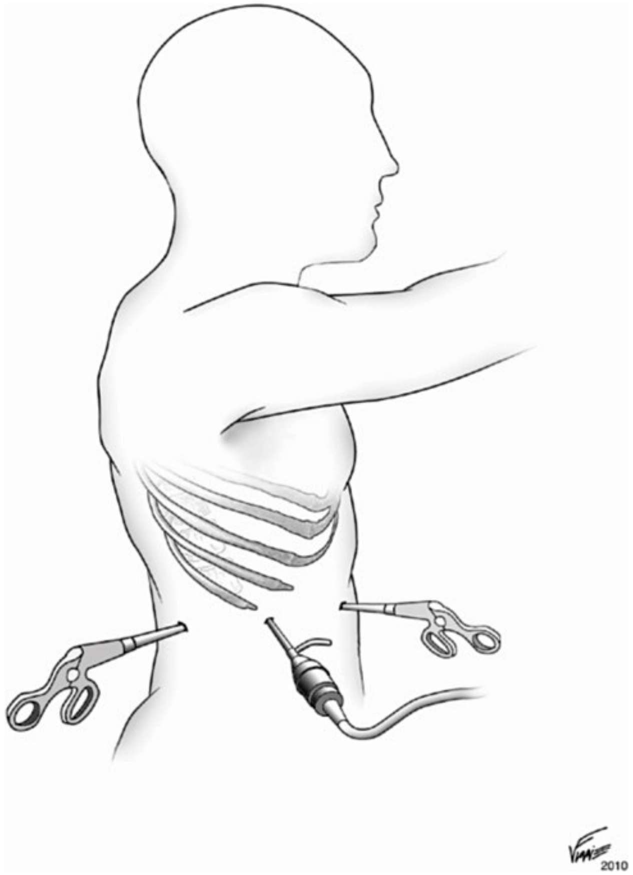

**Figure 84.2** Trocar placement for retroperitoneal renal/adrenal surgery. Patient is positioned in the full flank position. All three trocars line up in a straight line. *Source:* Urologybook.com. Reproduced with permission of Urologybook.com.

which will decrease the amount of torque on the trocar and surgeon fatigue during conventional retroperitoneoscopic cases. Ultimately, the surgical left trocar, camera trocar, and right trocar are all placed in a straight line, perpendicular to the midaxillary line, with slight modification if the posterior trocar is shifted cranially by surgeon preference (Figure 84.2).

In cases of robot-assisted laparoscopy via a retroperitoneal approach, an accessory trocar for bedside assistance can be placed inferior to either of the robotic trocar sites or triangulated inferiorly between the camera and robotic trocar sites (Figure 84.3a,b).

### Limitations of retroperitoneoscopic surgery

Limitations to the retroperitoneal approach to laparoscopic and robot-assisted laparoscopic surgery include the limited anatomic space both internally and externally. Patient anatomic variability may further limit the space between the costal margin and iliac crest and create a challenge for adequate trocar spacing for ease of triangulation. Furthermore, internal space in the retroperitoneum is dependent on the degree of peritoneal mobilization anteriorly with the balloon and manual dissections employed. As mentioned previously, size of the renal or adrenal mass, degree of hydronephrosis, or other pathology or anatomic variation may further limit the utility of the retroperitoneal space. In addition, because of the limited space in the retroperitoneum, camera mobility may be limited due to crossing of working instruments and avoidance of retroperitoneal fat and structures that may smudge the lens and blur visualization during the operation.

## Extraperitoneal pelvic access

### Patient evaluation and selection

Most radical prostatectomies are currently performed via a minimally invasive approach. Other urologic pelvic surgeries that can also be performed in a minimally invasive fashion include simple prostatectomy, radical cystectomy, partial cystectomy, and surgeries of the distal ureter. The majority of minimally invasive urologic pelvic surgery is performed via a transperitoneal approach, which provides increased working space and less instrument conflict. However, there are scenarios where an extraperitoneal approach may provide some distinct advantages. In patients with

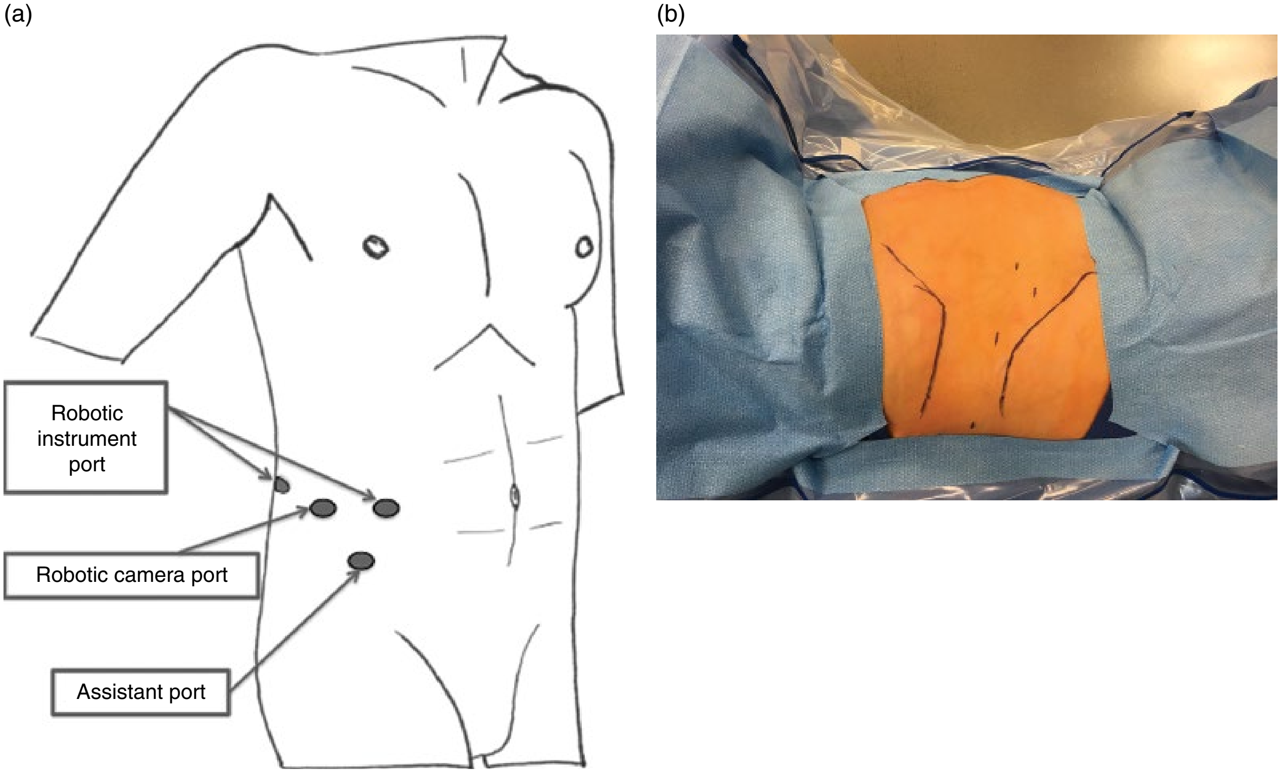

**Figure 84.3** (a) Diagram depicting trocar placement for robot-assisted retroperitoneal renal surgery with midaxillary line camera trocar, anterior and posterior robotic trocars, and inferior bedside assistant trocar. (b) Operating room positioning and markings depicting sites for planned trocar placement for robot-assisted retropertoneoscopic right partial nephrectomy.

previous abdominal surgery, the extraperitoneal approach avoids entry into the peritoneal cavity and obviates the need to perform an adhesiolysis, which could otherwise increase operative time. Although the risk of inadvertent bowel injury when performing minimally invasive urologic pelvic surgery is low overall, the risk increases in patients with previous abdominal surgery, inflammatory bowel disease, or previous peritonitis. Avoiding entry into the peritoneal cavity can reduce the risk of bowel injury in such patients. In transperitoneal pelvic surgery, the patients are often placed in the steep Trendelenburg position to help mobilize the bowel out of the pelvis. This extreme positioning is not required when performing the extraperitoneal approach because the peritoneum prevents the bowel from encroaching upon the pelvis and the surgeon's visual field [7]. Patients who are obese or have restrictive lung disease may not be able to tolerate the steep Trendelenburg position and in such scenarios, the extraperitoneal approach can be utilized to perform the surgery in a minimally invasive fashion. Finally, in the event of postoperative bleeding or urine leak, the hematoma or urinoma would be limited to the extraperitoneal space, which could minimize the development of associated intraperitoneal complications (i.e. ileus, distention, development of peritonitis, etc.). A randomized study comparing the approaches to robotic radical prostatectomy demonstrated no significant differences in any operative parameters analyzed and suggested that patients with prior abdominal operations would be best suited for the extraperitoneal approach [8]. In addition, a meta-analysis comparing extraperitoneal robotic radical prostatectomy and transperitoneal robotic radical prostatectomy showed a trend toward shorter operative times in the extraperitoneal patient cohort with equivalent oncologic outcomes [9].

Disadvantages to this approach include the smaller operative working space, which can increase conflict among working arms, especially if a fourth robotic arm is used. Moreover, there is limited access to the cepalad aspect of the pelvis, which can limit the surgeon's ability to perform an extended pelvic lymphadenectomy or access the ureter above the common iliac vessels. The extraperitoneal approach also results in a higher rate of pelvic lymphocele formation, many of which would otherwise be reabsorbed by the peritoneal cavity if a transperitoneal approach were used [10]. Scarring within the extraperitoneal space will limit the surgeon's ability to develop the working space. Because of this, the extraperitoneal approach should be avoided in patients who have undergone prior extraperitoneal pelvic surgery, such as inguinal hernia repair with mesh or renal transplantation.

## Patient positioning and placement of initial trocar access

After general anesthesia is established, the patient is then positioned for the operation. When the da Vinci Si is being used, the patient is placed in the dorsal lithotomy position to accommodate the robot in between the legs. With the newer da Vinci Xi model, the robot can be docked from the side of the patient and dorsal lithotomy is not required. The patient is adequately secured to the operating room table to allow for the Trendelenburg position; the method of patient securing is left to the surgeon's discretion. The authors have used the Pink Pad XL system (Xodus Medical Inc., New Kensington, PA, USA) with good success. After sterile preparation of the abdomen and genitalia, a Foley catheter is placed to decompress the bladder. The pubic bone is identified and a vertical, infra-umbilical incision of about 15 mm in length is made in the midline. S-retractors are used for retraction and dissection is continued through the subcutaneous tissue to the external fascial layer. Stay sutures of 0 Vicryl are placed in the rectus fascia, caudal and cephalad to the incision site on the fascia. Holding the lower fascia anteriorly, the fascia is incised. The rectus muscle belly is separated in the midline. A transversalis fascia below the arcuate line is identified and incised with scissors or blunt index finger dissection. The surgeon's index finger is then inserted into the preperitoneal space and the space is developed, taking care not to enter the peritoneal cavity superiorly. A kidney-shaped dissecting balloon (Covidien/Medtronic, Minneapolis, MN, USA) is inserted into the space in the direction of the pubic bone (Figure 84.4). The balloon is insufflated 30 times (~600 ml). Under direct laparoscopic visualization with a 10 mm laparoscope passed through the visual obturator of the balloon dissecting trocar, insufflation is continued until the pubic bone is visualized from within the dissecting balloon. After creating the operative space anterior to the bladder, the dissecting balloon is deflated and this trocar is removed. Care is taken to avoid disruption of the inferior epigastric vessels during insufflation which can be visualized with the angled lens laparoscope. A Hasson trocar of the surgeon's choice is then placed to serve as a camera trocar (10–12 mm caliber selected for specific laparoscopic or robot-assisted laparoscopic platforms).

## Placement of secondary trocars

Reflection of the peritoneum in a cephalad and lateral direction is often necessary to allow for placement of additional trocars. Using a 10 mm laparoscope with some gentle pressure, the peritoneum is swept in a cephalad and lateral direction to develop the working space.

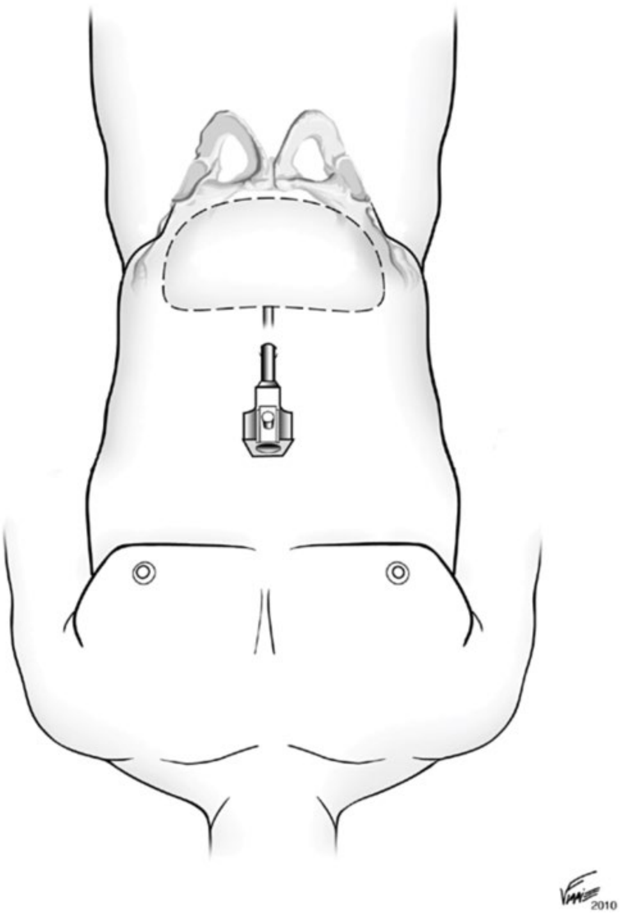

**Figure 84.4** Extraperitoneal balloon dissection for laparoscopic or robotic pelvic surgery. *Source:* Urologybook.com. Reproduced with permission of Urologybook.com.

Inadvertent entry through the peritoneum can occur, which can lead to gas escape into the peritoneal cavity and collapse of the working space. An attempt can be made to close the hole with a suture; alternatively, a small trocar can be placed in the peritoneal cavity to allow for slow decompression of the pneumoperitoneum. If these maneuvers prove ineffective, the surgeon should consider converting to a transperitoneal or an open extraperitoneal approach.

Prospective identification of the pulsations of the iliac vessels and inferior epigastric vessels should be performed to avoid inadvertent injury during dissection of the extraperitoneal space and trocar insertion, respectively. The standard robotic prostatectomy trocars are then placed, arching laterally and inferiorly and spaced approximately 7–8 cm from the camera trocar. A third robotic trocar can be placed lateral and inferior to one of the medial robotic trocars in one lower quadrant, and a bedside assistant accessory trocar can be placed on the contralateral lower quadrant. All robotic and accessory trocars should be placed under direct laparoscopic visualization to ensure safe entry into the preperitoneal space, avoiding critical vascular structures in the pelvis and anterior abdominal wall. Once the trocars are in place, the robot can be docked to the patient and the surgery can commence.

## Laparoscopic exit in retroperitoneal and pelvic extraperitoneal cases

Although great emphasis is placed on initial access for laparoscopic and robot-assisted laparoscopic cases, of equal importance is the exit or removal of trocars at the end of these procedures. It may be challenging for surgeons to follow through with these steps due to fatigue, but it is necessary for them to maintain vigilance at the end of the case. Herein, we describe the important features of exit from retroperitoneal and extraperitoneal surgery.

If an inadvertent entry into the peritoneum is recognized during retroperitoneal surgery, the surgeon should explore this area and ensure no injury to the bowel or other intraperitoneal organs has occurred. This may require expanding the defect in the peritoneal lining to fully visualize and assess the intraperitoneal space. Upon confirming integrity of all structures and hemostasis, the peritoneum can be reapproximated with a running absorbable stitch to re-establish the separation of the peritoneum and retroperitoneum. For extraperitoneal pelvic surgery it is prudent to create a small peritoneal window at the level of the umbilicus at the end of the case to expel pneumoperitoneum that may have accumulated. Often this window can be achieved using a small instrument puncture which does not require peritoneal lining closure.

The surgeon may decrease insufflation pressures to 10 mmHg or less to ensure no bleeding is visualized. It is standard practice to remove all trocars under direct vision. In the event of bleeding from trocar sites, a Carter–Thomason closing device may be used to close the fascia and obtain hemostasis. Large (≥12 mm) trocar sites may be closed with the Carter–Thomason closing device and Vicryl suture in a figure-of-eight fashion. In cases of extirpative surgery, the specimen extraction site should have complete fascial reapproximation to avoid hernia formation. Hernia formation is still a risk in extraperitoneal and retroperitoneal approaches, although this complication is relatively rare compared to transperitoneal laparoscopic procedures.

## Introduction

The introduction of hand-assisted laparoscopic surgery (HALS) has contributed greatly to the widespread adoption of laparoscopy for renal surgery. The adoption of laparoscopic renal surgery was very modest in the first decade following the initial report by Clayman et al. [1]. Why did laparoscopic nephrectomy take so long to catch on, but then subsequently become a standard procedure? This history of laparoscopic nephrectomy contrasts starkly with that of other laparoscopic procedures introduced in the same time period (late 1980s to mid 1990s). Laparoscopic cholecystectomy, laparoscopic pelvic lymph node dissection (until its utility was reduced by prostate specific antigen (PSA) risk profiling), laparoscopic gastric fundoplication, and laparoscopic hysterectomy all achieved widespread use soon after their introduction. Why was laparoscopic nephrectomy different? The primary reason proposed in the mid 1990s was that the necessary operative skills in laparoscopic nephrectomy were too difficult for the average urologist to develop and maintain, given the relative infrequency of nephrectomy in a typical urology practice. Other factors included concern about oncologic efficacy, the inefficiency of increased operative time, and safety of the procedure in case of vascular injury.

Although there likely were many developments that spurred on the widespread acceptance of laparoscopic nephrectomy, HALS was a major factor. HALS addresses many of the perceived problems: it simplifies the procedure technically, which allows even urologists with a low-volume practice to develop and maintain skills; it facilitates wide dissection and intact specimen removal, which may provide some reassurance as to the oncologic efficacy of the procedure (although there is no evidence that HALS provides any different outcome from standard laparoscopic nephrectomy in this regard); it reduces operative time for most surgeons; and it provides more rapid control of vascular injury, reducing the need for conversion to open surgery. Once a critical mass of surgeons started performing laparoscopic nephrectomy, combined with patient demand, its popularity was inevitable.

Following a brief history of hand assistance, this chapter describes the HALS devices that are currently available along with some general principles of their application. The results of HALS are then provided with emphasis on series that compare HALS to other laparoscopic techniques. Finally, the role of HALS in urology is assessed.

## History

As with many innovations in surgery, initial forays into HALS were met with skepticism [2]. In 1993, Boland et al. reported their experience (starting in 1992) with insertion of a gloved hand through a tight fascial incision to allow direct manual organ dissection and removal while maintaining pneumoperitoneum during laparoscopy [3]. Tierney et al. [4] and Tschada and Rassweiler [5] reported laparoscopic radical nephrectomy using this technique in 1994 and 1995, respectively. Commercial devices to facilitate laparoscopic hand assistance were under development by this time [6], and in 1996 Bannenberg et al. [7] reported hand-assisted laparoscopic nephrectomy in a porcine model using a prototype of the first commercial HALS device. Later that same year, Nakada et al. [8] performed the first clinical laparoscopic nephrectomy with a commercial HALS

Companion website: www.wiley.com/go/smith/textbookofendourology

device. In 1997, Keeley et al. [9] reported the first HALS nephroureterectomy, and in 1998 Wolf et al. [10] described the first HALS donor nephrectomy. HALS was soon applied to a number of other urologic laparoscopic procedures. The introduction of improved commercial HALS devices that did not require the use of a sleeve further accelerated the acceptance of HALS in urology.

## Devices for hand-assisted laparoscopy

The first commercial HALS devices, such as the Pneumo Sleeve (Dexterity Surgical, Roswell, GA, USA) and the Intromit (Medtech Ltd., Dublin, Ireland), had sleeves that wrapped around the arm and were affixed to the abdomen with adhesive. The HandPort (Smith & Nephew, Andover, MA, USA) also had a sleeve, but the base was held on the abdomen with inflatable compression rather than adhesion. None of these devices remains in production. Lessons learned through their use, however, prompted the development of improved devices that did not require a separate sleeve.

There are two commercial devices for HALS currently available. The Gelport® (Applied Medical, Rancho Santa Margarita, CA, USA; Figure 85.1a) has two components that fit together on the abdomen, affixed by compression and providing gas occlusion with a gel that fits snugly around the surgeon's forearm. The Dextrus™ Access Port (Ethicon Endo-surgery, Cincinnati, OH, USA; Figure 85.1b) replaced the Lap Disc®, which was of similar design. It also has two components and is held within the abdominal incision by compression, but the gas occlusion is achieved with an iris valve that closes around the surgeon's forearm. A final second-generation device, the Omniport (Advanced Surgical Concepts, Wicklow, Ireland), was a cylinder that inflated to provide both abdominal fixation and gas occlusion; it is no longer manufactured.

### Gelport

The Gelport kit contains the Alexis® wound retractor, which is a pair of plastic rings connected by a flexible skirt that holds the abdominal incision open and provides the base for the second component, and the Gelseal® cap, which snaps onto the outer ring of the

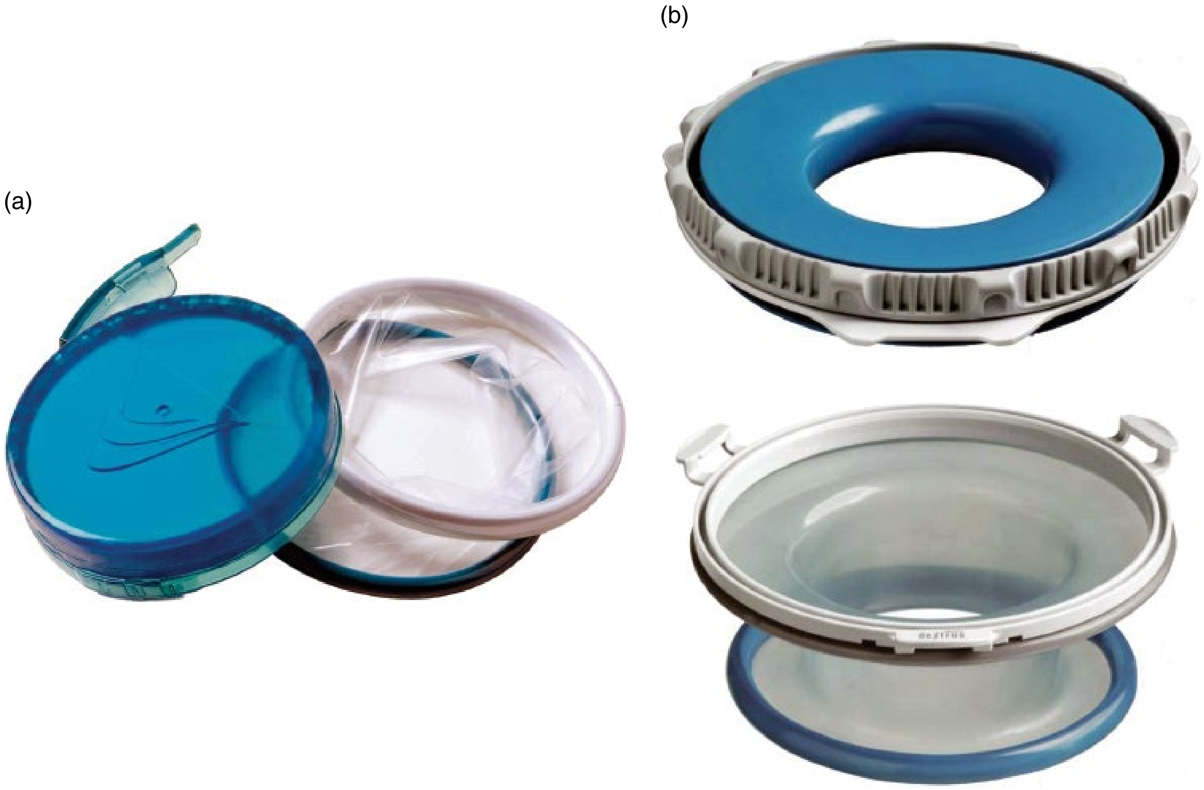

**Figure 85.1** (a) Gelport. *Source:* Applied Medical Resources Corporation, USA. Reproduced with permission of Applied Medical Resources, USA. (b) Dextrus Access Port. *Source:* Ethicon Endo-Surgery, Cincinnati, USA. Reproduced with permission of Ethicon Incorporated, USA.

wound retractor to provide a gas-tight seal through which a hand or laparoscopic ports can be placed. The abdominal incision is made initially, and then the flexible ring of the wound retractor is inserted into the abdomen, leaving the rigid ring outside (Figure 85.2). The outer ring is rotated inward to shorten the skirt and pull the rings tight against the abdominal wall. Once the gel cap is snapped onto the outer ring, the abdomen is gas tight (Figure 85.3). The gel expands enough to allow insertion of a hand through its central slit (Figure 85.4), but also will occlude the incision with nothing passing through it. In addition, ports can be passed through the central slit in the gel, or through a separate stab incision in the gel. An instrument can be passed through the gel alone, or when the hand is in place. See Video 85.1, which demonstrates use of the Gelport kit during a HALS nephrectomy.

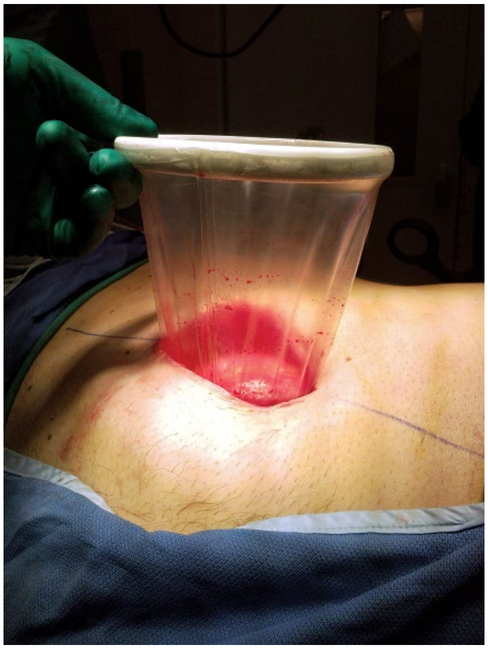

**Figure 85.2** Gelport kit: the flexible ring of the Alexis wound retractor is inserted into the abdomen, leaving the rigid ring outside.

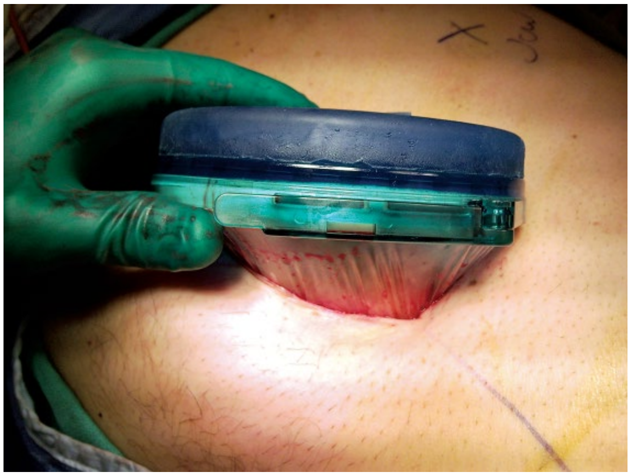

**Figure 85.3** Gelport kit: the gel cap has been attached and maintains pneumoperitoneum even without the hand through the device.

## Dextrus Access Port

The Dextrus Access Port is also a two-piece device. The base is a fixed-length wound retractor composed of an inner flexible ring and an outer rigid ring connected by an elastic skirt that holds the abdominal incision open and provides the base for the second component. The outer cap is a pair of locking rings that snap onto the base and close an iris valve to provide gas occlusion. The fixed-length wound retractor, which is available in three sizes to accommodate abdominal walls of varying thickness, is inserted into the abdominal incision by slipping the flexible inner ring inside the abdomen (Figure 85.5), with the tension from the elastic sheath holding the rigid outer ring stable on the abdominal wall. The outer cap is then snapped onto the wound retractor. For intra-abdominal use, the hand is inserted to the desired depth and the iris valve is tightened around the forearm by turning the outermost ring clockwise and fixing it in place by way of ratcheted teeth (Figure 85.6). Slight inward movements of the forearm can be made, but large movements require that the iris valve be opened a bit. Similarly, pulling back or removing the forearm necessitates tightening the valve to prevent gas leak. The valve can be completely occluded (Figure 85.7) or it can be tightened around a port or laparoscopic instrument.

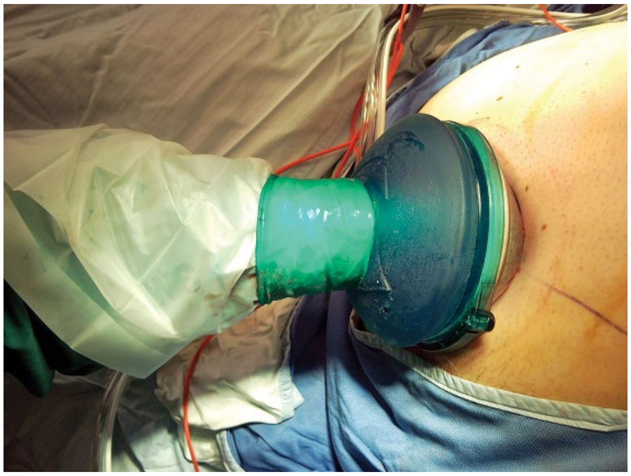

**Figure 85.4** Gelport kit: the intra-abdominal hand is inserted through the central slit of the gel cap.

### Adjuncts

Fluid can sometimes track up the intra-abdominal forearm and soak through the surgeon's gown above the glove. Double gloving does not necessarily prevent this and some additional barrier is recommended. We have found the simplest and most effective to be a Steri-Drape™ Small Towel Drape 1000 (3 M Company, St. Paul, MN, USA). The adhesive strip is wrapped around the wrist and the rest of the drape trails down over the forearm, covered by a second glove over the hand and adhesive strip (Figure 85.4). The second glove should be dark to minimize glare. The Dextrus Access Port comes packaged with a plastic wrap that serves the same function. Other surgeons have overcome the fluid problem by using a disposable fluid-impervious gown.

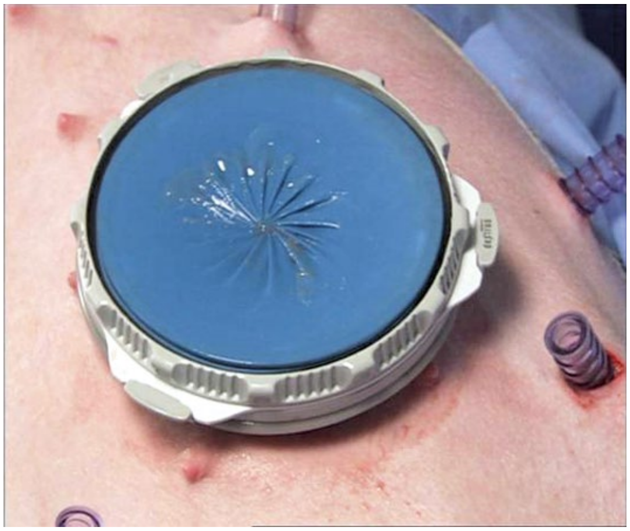

**Figure 85.7** Dextrus Access Port: the iris valve can be completely occluded. *Source:* Ethicon Endo-Surgery, Cincinnati, USA. Reproduced with permission of Ethicon Incorporated, USA.

Surgical instruments can be placed into the abdomen for use by the intra-abdominal hand. Small, open surgical instruments, including Atson forceps and short Satinsky clamps, have been used intra-abdominally during HALS. Of these, the most useful may be hand-held bulldog clamps for temporary vascular occlusion.

## General techniques for hand-assisted laparoscopy

### Choice of position for surgeon, HALS device, and ports

Although the application of HALS to retroperitoneoscopic surgery has been reported, it is not a widely performed technique. This section, pertaining to technique, will not address retroperitoneoscopic HALS, although the few reported series are included in the section on results. See Video 85.1, which demonstrates our technique for nephrectomy using HALS.

Either the primary or the assistant surgeon can use their hand intra-abdominally. When the primary surgeon's hand is intra-abdominal, direct manual dissection is possible. However, the primary surgeon then has only one hand free to manipulate a laparoscopic instrument. If the assistant's hand is in the abdomen, the primary surgeon can use two laparoscopic instruments and the intra-abdominal hand is used primarily for retraction. This distinction is important because it can alter port placement. Figure 85.8 indicates the most common HALS device and port arrangements for HALS renal surgery when the surgeon's hand is intra-abdominal. Figure 85.8a is the most typical arrangement for left-sided renal surgery by a right-handed surgeon. The nondominant (left) hand is placed through the HALS device in the periumbilical midline. This allows simultaneous retraction of bowel and finger dissection of the kidney. The assistant operates the videolaparoscope through a port at the level of the umbilicus, 1–2 cm lateral to the edge of the HALS device (**2** in Figure 85.8a), and an instrument placed through a lateral assisting port (**4** in Figure 85.8a). The surgeon's working port is placed 1–2 cm below the costal margin (**3** in Figure 85.8a), on the line that extends from the videolaparoscope port to the patient's ipsilateral shoulder. There is more variation for right-sided renal surgery by a right-handed surgeon. Some, including these authors, recommend an arrangement that is the mirror image of the left-sided procedure (Figure 85.8b). The right hand is used intra-abdominally, which allows retraction of the liver by the back of the hand while dissecting the kidney. The surgeon's left hand is used to manipulate laparoscopic instruments, which some right-handed surgeons find awkward. The ability to use either hand intra-abdominally is valuable, and if an "ambidextrous" approach is used when starting out with HALS, then it is quickly learned. Some portions of the procedure are facilitated by using a different hand in the abdomen, on either side, so it is helpful to be ready to use either hand intra-abdominally.

An alternative for right nephrectomy by a right-handed surgeon is depicted in Figure 85.8c. Here, the surgeon's left hand is placed through the HALS device and the right hand operates an instrument through the working port (**3** in Figure 85.8c). The assistant operates the videolaparoscope (**2**) and an assisting instrument (**4**). Some place the HALS device obliquely in the ipsilateral lower quadrant when using this approach. A number of HALS device placements have been described, including midline (supra-, peri-, and infra-umbilical), paramedian, subcostal, lower quadrant oblique ("muscle-splitting" Gibson incision), and transverse suprapubic (Pfannenstiel). Each will be associated with slightly different port placements, depending on whether the intra-abdominal hand is the surgeon's or assistant's, and whether the left or right hand is preferred. The general principles that guide device and port placement in HALS are: maximization of effectiveness of the hand, minimization of videolaparoscope obstruction by the hand, and centering the videolaparoscope between instruments rather than working with the hand and instruments all off to one side. Use of a 30° videolaparoscope is very useful during HALS to reduce obstruction of vision by the intra-abdominal hand.

## Tips and tricks

HALS facilitates transfer of skills from open surgery to laparoscopic surgery. Although this is an easier step to make than that from open surgery to standard (non-hand-assisted) laparoscopic surgery, HALS does require a distinct skill set. In this section, some techniques that are different from those used in open surgery and standard laparoscopic surgery are highlighted.

A laparoscopic port can be inserted through both the Gelport and the Dextrus Access Port, and the Gelport will accommodate several ports or a hand and additional ports. This allows inspection of the abdomen laparoscopically before secondary port placement. Ports can be inserted under direct visualization, or a hand can be placed through the HALS device and the ports can be inserted directly onto the intra-abdominal hand (Video 85.1). This maneuver should be performed only with noncutting trocars and only after visual inspection has confirmed the inner abdominal wall to be free of adhesions.

After placing the HALS device and ports, a laparotomy pad is placed into the abdomen. This can be used to soak up fluid and blood, either by itself (when it is not yet saturated) or by compressing it with the hand and using a laparoscopic aspirator to remove fluid through the pad. Some surgeons place a hemostat on the blue tag of the laparotomy pad to prevent its complete placement into the abdomen. We prefer to place the entire pad inside the abdomen to allow its unrestricted use, but we do cut off part of the blue tag and clamp it to the drapes as a visual reminder that a pad is inside the abdomen.

Performing multiple tasks simultaneously with the intra-abdominal hand takes greatest advantage of its presence. Retraction and exposure can be obtained in several directions at once, or the hand can simultaneously retract and dissect. One of the most useful multitasking hand positions is the "C" position (a term coined by Stephen E. Strup MD) for dissection medial to the lower pole of the kidney and at the renal hilum (Figure 85.9). Using the left hand for left renal surgery, or the right hand for right renal surgery, the forearm is placed parallel to the great vessels, palm lateral, wrist flexed 45–90°, index finger lifting the kidney, thumb exerting inferomedial traction on tissue, and the middle fingers extended. This position allows simultaneous retraction of bowel with the back of the hand, elevation of the lower pole, and dissection with the fingers. When the hand is elevating the lower pole, an irrigator–aspirator probe or some other instrument can be placed through an assisting port to help in the dissection.

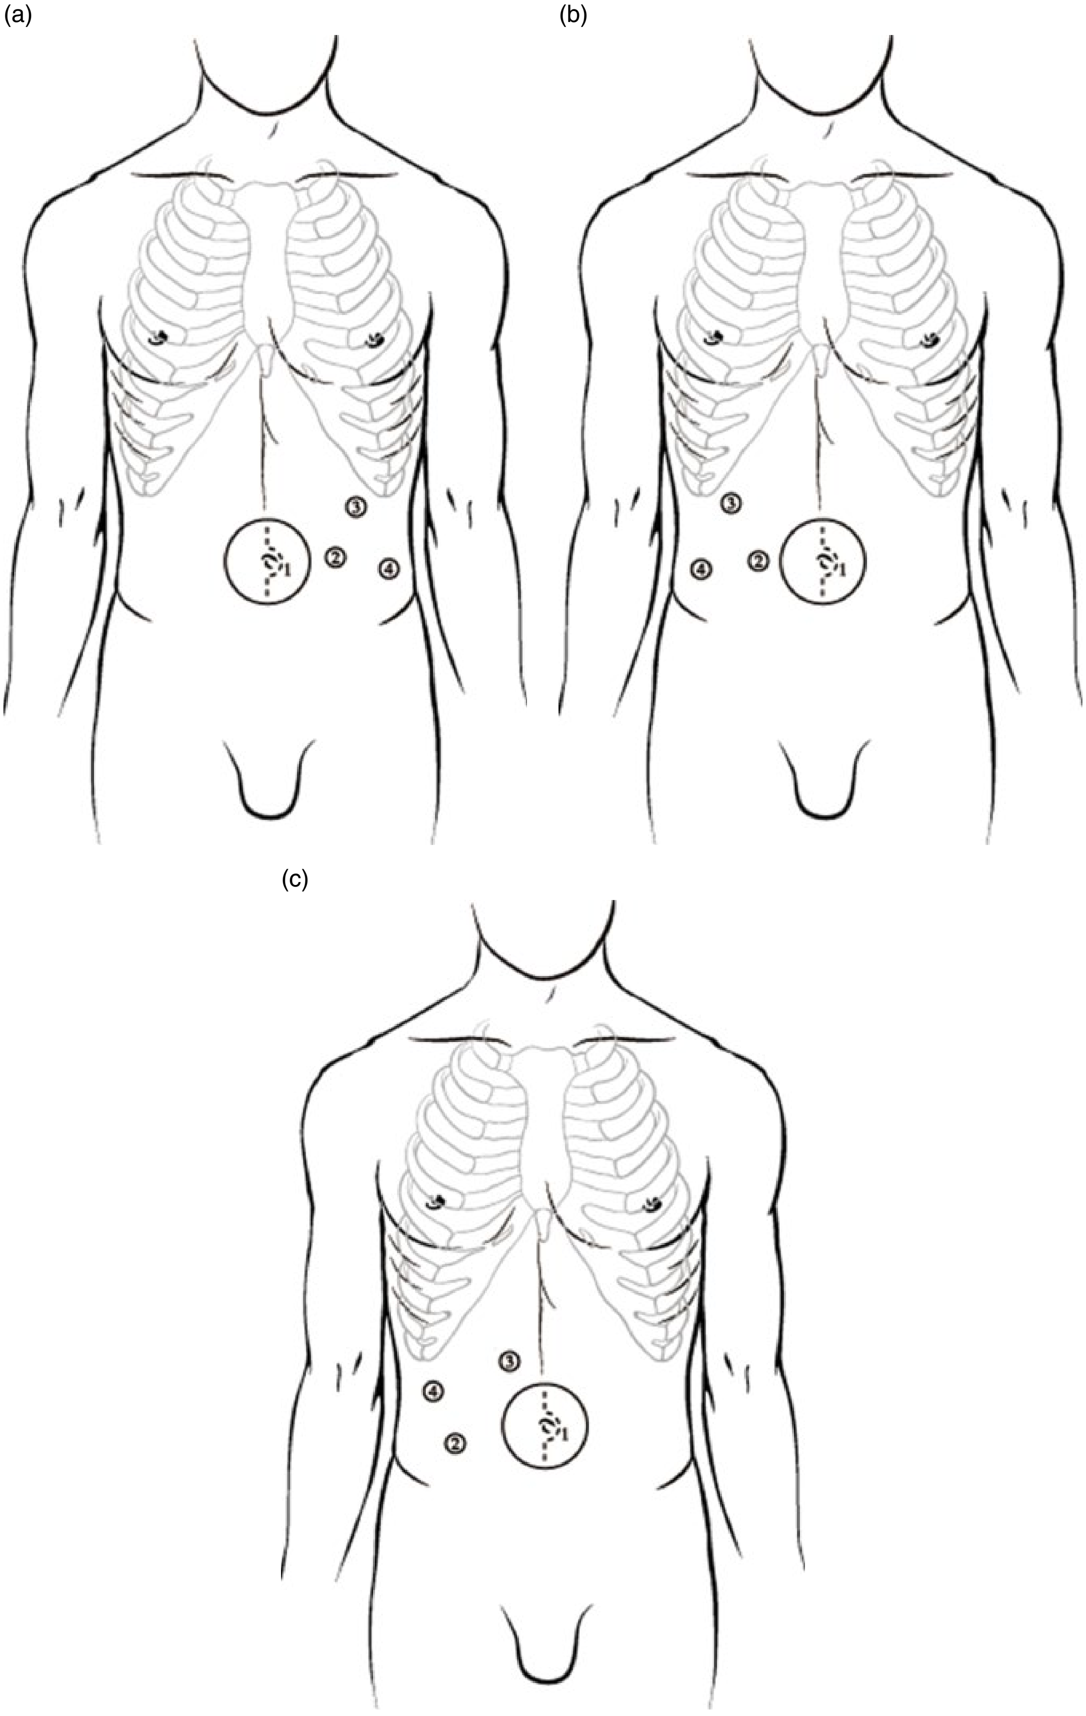

**Figure 85.8** (a) Typical port placement for left hand-assisted laparoscopic surgery (HALS) nephrectomy using the surgeon's left hand in the abdomen. (b) Mirror image, for right HALS nephrectomy using the surgeon's right hand in the abdomen. (c) One alternative for right HALS nephrectomy using the surgeon's left hand in the abdomen. 1, HALS device; 2, videolaparoscope port; 3, working port for surgeon; 4, assisting port.

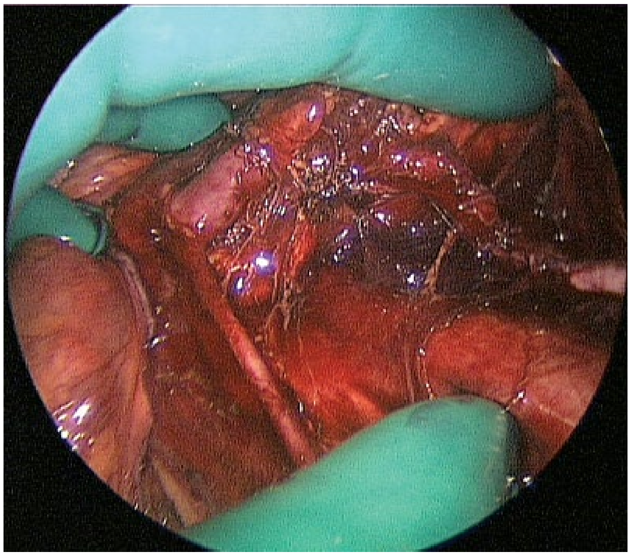

**Figure 85.9** The "C" position. Left hand placed through a midline HALS incision, for left nephrectomy.

When dissecting out the renal hilum, the renal artery and vein can be encircled en bloc with the thumb and forefinger of the intra-abdominal hand. After sharply dissecting tissue cephalad to the renal vein, it is usually easy to bluntly place the index finger cephalad to the renal vein, wiggle it in a posterior direction until the psoas muscle is touched, and then scoop inferiorly to gather up the entire renal hilum. This maneuver is safe as long as a careful touch is used, sensing resistance that indicates an early branch or an accessory vessel. Encircling the hilum in this way provides the ability to rapidly control it in case of vascular injury, and with this added confidence the subsequent hilar dissection can proceed rapidly. This maneuver is less useful if the intention is to remove the adrenal gland with the specimen (on the left side), as it is not safe to perform blunt dissection medial to the adrenal gland.

## Results of hand-assisted laparoscopic surgery

### Series

In urology, HALS is most commonly applied to nephrectomy. The first reported use of HALS in urology was for radical nephrectomy [4], as was the first use of a commercial HALS device in urology [8]. In one of the earliest large series of HALS for radical nephrectomy, Stifelman et al. [11] reported 95 HALS radical nephrectomies for large specimens. The mean operative time was 158 min and the major complication rate was only 4%, with a rate of conversion to open surgery of 3%. The oncologic efficacy of HALS radical nephrectomy has been confirmed in several series with long-term follow-up. Bandi et al. [12] reported 5-year recurrence-free survival of 90% after 65 HALS radical nephrectomies with more than 3-year follow-up. Harano et al. [13] reported a 4-year recurrence-free survival of 88% in a series of 96 patients. At the University of Michigan, the 5-year recurrence-free survival in a series of 108 patients with a mean tumor size of 6.9 cm was 82% [14]. Kawauchi et al. [15] reported a 5-year recurrence-free survival of 92% among 123 patients. Recently, Park et al. [16] provided updated follow-up of the largest series reported to date of HALS radical nephrectomy with long-term follow-up. Their multi-institutional series from 26 centers in Korea involving 197 patients demonstrated a 5-year recurrence-free survival of 95% with a median follow-up of 69 months.

There have been 21 series (containing 10 or more patients) of HALS nephroureterectomy for upper tract urothelial neoplasms (not including series that have been updated by subsequent ones) published through 2015 [17–37]. In the total of 832 patients described in these series, the operative time averaged 253 min, with 7% major and 13% minor complication rates overall (when reported). Conversion to open surgery was required in only 2.1% of cases. The nonvesical recurrence rate was 13% with 24-month mean follow-up. A description of the long-term outcome of HALS nephroureterectomy for urothelial carcinoma from the University of Michigan includes 62 patients with a median follow-up of 77 months: the 5-year cancer-specific survival was 89% for low-grade disease and 72% for high-grade disease [38].

Many of the recently reported series of donor nephrectomy have been with HALS. Among the 14 such series containing 100 or more patients, reporting 2850 patients in total, the mean operative time was 174 min and the mean warm ischemia time 2.7 min [39–52]. The minor and major complication rates were 7.2% and 3.0%, respectively, with a conversion to open surgery in only 0.8% of patients. In the studies that reported convalescence, the mean time to return to nonstrenuous activity levels was 24 days. In the largest series to date, Rajab and Pelletier [53] reported long-term follow-up of nearly 1500 patients. Of patients, only 0.9% experienced graft loss within one month of transplant. A total of 1.4% of patients developed delayed graft function with subsequent recovery of function. 10-year death-censored graft survival was approximately 80%. Of the first 200 HALS donor nephrectomies performed at the University of Michigan, the 1-month, 1-year, and 3-year actuarial graft survival rates are 97%, 95%, and 94%, respectively [42]. On review of 480 consecutive cases of HALS donor nephrectomy, Gabr et al. [54] reported a ureteral complication rate of 3.7%, and noted that ureteral complications were associated with increased donor age and the lack of ureteral stent placement at the time of transplant.

Other reports of HALS for renal surgery include partial nephrectomy [55–59], heminephrectomy (horseshoe kidneys, duplicated upper tracts, etc.) [60–63], bilateral nephrectomy [64–72], and bilateral partial nephrectomy [73]. Bilateral nephrectomy for autosomal dominant polycystic kidney disease is particularly challenging with standard laparoscopic techniques, and is perfectly suited to HALS. Other difficult maneuvers, such as radical nephrectomy with associated excision of renal vein or vena caval thrombus [74–79], and removal of kidneys with xanthogranulomatous pyelonephritis or other inflammatory or unusual conditions [76, 80–85], are facilitated by HALS.

HALS in urology is most commonly applied to renal surgery, but there have been reports of its use for other organs as well. Similar to its use for bilateral nephrectomy, HALS facilitates multiorgan removal for other entities [86–89]. Laparoscopic adrenalectomy is usually well-performed with standard transperitoneal or retroperitoneoscopic techniques, but in cases of large specimens or as an alternative to conversion to open surgery, HALS does have a role in the management of adrenal disease [90–94]. Minimally invasive cystectomy is growing in popularity. Even when using standard or robot-assisted techniques, many surgeons prefer to create at least part of the urinary diversion via a mini-laparotomy. Given this, several groups have reported using this mini-laparotomy incision for a HALS device, and performing the cystectomy or pelvic exenteration with HALS techniques [95–100]. HALS for other procedures, such as ureterolysis [101], retroperitoneal lymph node dissection [102], and resection of local renal cell carcinoma recurrences [103], has been described.

## Comparisons to other techniques

Although HALS has been reported via the retroperitoneoscopic route for renal surgery [20, 28, 31–33, 104–111], this is not a commonly performed technique. Because of this, when assessing the role of HALS in urologic laparoscopy, this chapter considers it to be a transperitoneal approach. Transperitoneal HALS, standard transperitoneal laparoscopy, and standard retroperitoneoscopy all have advantages and disadvantages. In this section, comparisons between the techniques are presented.

Wolf et al. [112] reported the initial comparison of hand-assisted and standard transperitoneal laparoscopic nephrectomy in 1998, using the first hand-assisted ($n = 13$) and standard ($n = 8$) transperitoneal laparoscopic nephrectomies performed at the University of Michigan and the University of Wisconsin. The mean operative time for hand assistance was 90 min shorter than that for standard laparoscopy. This comparison suggests that early in a surgeon's experience, HALS "shortens the learning curve" for transperitoneal nephrectomy. A subsequent report from the University of Michigan made the same comparison after more experience had been gained, and revealed that after an experience of approximately 20 laparoscopic radical nephrectomies, the advantage of HALS over standard laparoscopy in terms of operative time fell to only 30 min [113].

A recent meta-analysis of studies comparing HALS to open and standard laparoscopic approaches for urologic procedures produced similar results to previous publications [114]. This meta-analysis reviewed 62 studies of donor nephrectomy [30], radical nephrectomy [21], and nephroureterectomy [14], which totaled 5446 patients. For donor nephrectomy, HALS was associated with less intraoperative blood loss when compared with open and standard laparoscopic approaches. Length of stay was shorter compared to the open cohort, while operative and warm ischemia times were shorter compared to the standard laparoscopic group. Yuan et al. [115] limited their meta-analysis to donor nephrectomy and included 4 additional years of studies with over 2000 patients total, and found similar results. They noted no increase in donor complications or recipient graft function.

In a randomized trial of HALS versus standard donor nephrectomy (20 in each group), Bargman et al. [116] found that operative time was significantly less with the standard approach (219 vs. 200 min, $P = 0.02$), but that there were no differences in estimated blood loss, warm ischemia time, length of postoperative stay, analgesic use, rate of complications, pain scores on postoperative days 1 and 2, or quality-of-life scores at 1 and 3 months. Of note, all nephrectomies in this series were performed by a surgeon with extensive experience in both HALS and standard laparoscopy, including more than 100 laparoscopic donor nephrectomies and more than 500 other laparoscopic renal operations prior to the study period. This is consistent with the data reported above; with experience, some advantages of HALS over standard laparoscopy (such as reduced operative time) diminish.

There have been two prospective trials involving HALS for radical nephrectomy. Nadler et al. [117] in a comparison of standard transperitoneal, standard retroperitoneal, and HALS (11 in each group; not randomized but prospectively enrolled in alternating fashion) found that operative time was significantly lower in the HALS group, and that hospital stay and time to normal daily activity were significantly shorter in the standard transperitoneal group. Intraoperative blood loss, postoperative narcotic use, and time to oral intake were similar in all three groups. Although there were no differences in early complications, incisional hernias occurred only in the HALS group. In a multi-institutional randomized trial comparing HALS (9 patients) versus standard transperitoneal laparoscopic

(12 patients) radical nephrectomy, Venkatesh et al. [118] found no differences in operative time. Although the meta-analysis by Wadström et al. [114] was not able to compare HALS to standard laparoscopy because of a limited number of studies, they did report improved blood loss and length of stay with HALS when compared to open radical nephrectomy.

As noted above, series of surgeons' early experience with standard laparoscopic and HALS nephrectomy often suggest a lower complication rate with HALS [112, 119], but as experience is gained the overall complication rates of the two approaches become similar. However, the intra-abdominal hand does appear to reduce some specific complications, in particular the need to convert to open surgery. Silberstein and Parsons found this in their meta-analysis [120]. At the University of Michigan, 196 standard laparoscopic radical nephrectomies were compared with 154 HALS radical nephrectomies [121]. There were no conversions to open surgery from HALS but conversion to open surgery occurred in the standard laparoscopic group in 0.8% of nonobese, 3.0% of obese, and 17% of morbidly obese patients. The difference was statistically significant in the latter two groups. In addition, the availability of HALS provides an alternative to conversion from standard laparoscopy to open surgery; converting to HALS from standard laparoscopy may allow the procedure to be completed in a minimally invasive fashion [122, 123].

Conversely, some complications appear to occur more commonly in association with HALS than with standard laparoscopy. Troxel and Das [124] noted a 6% rate of incisional herniation at the HALS site in a series of 50 HALS radical nephrectomies. Terranova et al. [125] reviewed 54 patients undergoing HALS renal surgery, and reported complications related to the HALS incision in 9.3%, including infection, herniation, skin incisional breakdown, fascial dehiscence, and enterocutaneous fistula. Montgomery et al. [126] reviewed 424 consecutive HALS renal procedures and reported similar findings, including infection in 6.8%, incisional hernia in 3.5%, and fascial dehiscence in 0.5% of HALS incisions. Although direct comparative data are limited, some reports suggest an increased wound complication rate with HALS compared to standard laparoscopy. Overall, wound infections and hernias appear to occur less frequently in association with HALS than with open surgery, but more often than in association with standard laparoscopy. In one literature compilation which included 56 reports, there was a significantly greater wound complication rate associated with HALS compared to standard laparoscopy (1.9% vs. 0.2%, $P < 0.05$) [127].

Data comparing the duration and intensity of convalescence after HALS compared to standard laparoscopy are less consistently reported than more objective outcomes, and are subject to bias in retrospective studies. In both of the prospective trials involving HALS for radical nephrectomy described above, there was some measure of a longer and/or more intense recovery period in the HALS patients. Nadler et al. [117] found the hospital stay to be 2.1 days after standard transperitoneal laparoscopy compared to 3.4 days after HALS radical nephrectomy. Narcotic use tended to be less in the former group, but the difference was not significantly different. In their multi-institutional randomized trial comparing standard transperitoneal laparoscopic and HALS radical nephrectomy, Venkatesh et al. [118] found a significantly longer time to return to normal activity and to work in the HALS group, although there were no differences in hospital stay or narcotic use. In a retrospective but large comparison of the two approaches to radical nephrectomy (113 standard laparoscopic, 158 HALS), Matin et al. [128] found longer hospital stay (4 vs. 2 days) and more narcotic use in the HALS group. In another retrospective but large study (147 standard laparoscopic and 108 HALS), Gabr et al. [121] found that hospital stay was longer (by a mean of 0.4 days) and time to return to nonstrenuous activity was greater (by a mean of 3.1 days) in the HALS group.

In addition to patient-related outcomes, HALS appears to have a distinctive surgeon-related impact. Johnston et al. [129], describing a survey of 25 urologists involved in lapararoscopic fellowship programs, reported that HALS was associated with significantly more hand/wrist, forearm, and shoulder pain compared to standard laparoscopy. Conversely, there was significantly more neck pain associated with standard laparoscopy. There was no significant difference between the approaches in terms of lower back pain. Gofrit et al. [130] found similar results in a survey of 73 members of the Endourology Society. HALS was associated with more pain involving the fingers, hand/wrist, and forearm/elbow than standard laparoscopy, while standard laparoscopy was associated with more complaints about neck pain. There were no major differences with regards to shoulder, upper back, and lower back pain. This survey also included questions about robotic surgery. Overall, robotic surgery was associated with the fewest complaints of pain and HALS was associated with the most. The work of Ost et al. [131] suggests one possible mechanism for the increased hand, wrist, and forearm pain with HALS. These investigators used oxygen sensors to measure oxygen saturation in the hand during HALS nephrectomy, and found that a report of hand pain during HALS nephrectomy was associated with hypoxia of the hand, down to 56–88% local oxygen saturation.

Overall, then, published data suggest that HALS is generally faster than standard transperitoneal laparoscopy, but that the difference decreases with increasing surgeon experience. The relative impact of HALS on operative time also appears to vary with the specific procedure. For advanced procedures, HALS appears to reduce the likelihood of conversion to open surgery, and converting to HALS is a good alternative to converting to open surgery when standard laparoscopy cannot be continued. There are important disadvantages of HALS to be acknowledged. The larger incision for HALS is associated with rates of infection and herniation that probably exceed those for standard laparoscopy. The intensity and duration of postsurgical recovery is slightly greater with HALS compared to standard laparoscopy, although the magnitude of the difference between HALS and standard laparoscopy is much less than that between HALS and open surgery. Finally, the surgeon pays a price during HALS in terms of increased upper extremity pain compared to standard or robot-assisted laparoscopy.

## Selective use of hand-assisted laparoscopic surgery

The advantages and disadvantages of HALS are listed in Box 85.1. The relative impact of these considerations differs according to surgeon and procedure. The general situations in which HALS is most useful are listed in Box 85.2. HALS is an excellent choice when intact specimen removal is required, as it takes advantage of the required incision throughout the entire procedure rather than just at the conclusion. Another major consideration is surgeon experience, with laparoscopy in general or with a new procedure. HALS is an excellent way for an inexperienced surgeon to start performing laparoscopy, or for an experienced surgeon to start performing a new procedure. Similarly, a difficult procedure is a good indication for HALS. Large specimens, reoperation, a perihilar mass, or anytime the surgical planes or tissue identification are indistinct can result in a prolonged and complication-prone laparoscopic procedure. HALS can make the difference between conversion to open surgery and completion of the minimally invasive procedure. Finally, for a patient with severe chronic obstructive pulmonary disease or congestive heart failure, in whom a rapid procedure is necessary because of problems owing to hypercapnia or elevated intra-abdominal pressure, HALS can be very useful.

With these considerations in mind, HALS is best selected when there is a clear advantage (in terms of operative time, safety, specimen manipulation, etc.) over standard laparoscopic techniques. The balance between the advantages and disadvantages of HALS is best determined by the individual surgeon and patient using shared decision-making. The best procedures for HALS are advanced extirpative renal procedures. For radical nephrectomy, HALS has most advantage when the specimen is large or the anatomy is difficult. For partial nephrectomy, HALS might facilitate accurate resection, collecting system repair, and/or hemostasis for tumors that are hard to access. For straightforward radical nephrectomies, and for partial nephrectomy for accessible tumors, standard transperitoneal or retroperitoneal techniques are effective in the hands of many. During procedures where intact specimen removal is required, such as nephroureterectomy for urothelial carcinoma or live donor nephrectomy, HALS takes advantage of the required incision throughout the entire procedure rather than just at the conclusion.

For some procedures HALS is less useful, or may even be a hindrance. Laparoscopic simple nephrectomy can be

**Box 85.1 Advantages and disadvantages of hand-assisted laparoscopic surgery compared to standard laparoscopy.**

### Typical advantages

- Faster
- Easier
- More control in operating room by surgeon
- Better control of vascular injury
- Reduced need for conversion to open surgery
- Enhanced teaching

### Typical disadvantages

- Larger incision
- Sometimes necessitates suboptimal port placement
- Hand can get in the way
- Increased wound complication rate
- Slightly greater intensity and duration of convalescence
- More upper extremity pain for surgeon

**Box 85.2 General situations in which hand assistance is most useful.**

- Intact specimen removal is required
- Limited experience:
  - With laparoscopy in general
  - With specific procedure
- Difficult procedure
  - Large specimen
  - Reoperation
  - Perihilar mass that limits access to vasculature
  - Other processes (inflammation, fibrosis, etc.) that render dissection difficult
- Medical comorbidities necessitate rapid procedure

performed in a straightforward manner with standard transperitoneal or retroperitoneal techniques unless the specimen is inflamed (e.g. pyonephrosis or xanthogranulomatous pyelonephritis) or very large (e.g. autosomal dominant polycystic kidney disease). Standard laparoscopic techniques are also adequate for renal cyst resection and adrenalectomy in most cases. For reconstructive procedures such as laparoscopic pyeloplasty or nephropexy, there is little advantage to HALS. Although there has been some interest in HALS for pelvic procedures, most urologists use a standard or robot-assisted laparoscopic approach to minimally invasive pelvic surgery.

## Conclusions

HALS is technically easier than standard laparoscopy, with a "shorter learning curve" for most procedures. The current devices are easily applied and effective. Although there is considerable variation in port placement, especially with regard to right nephrectomy for right-handed surgeons, the general techniques are standardized. Unless there is extensive laparoscopic experience, HALS offers more rapid operating times and a tendency toward lower need for conversion to open surgery than standard laparoscopy for most extirpative renal procedures. These advantages come at the price to the patient of slightly greater intensity and duration of convalescence, and an increased wound complication rate, compared to standard laparoscopy. The surgeon is at greater risk of suffering upper extremity pain. Given prior experience, HALS offers minimal if any improvement over standard laparoscopy for straightforward renal procedures, reconstructive procedures, and most pelvic procedures. HALS is most useful for difficult extirpative laparoscopic procedures, and when intact extraction is desired.

## Introduction

Laparoscopic techniques (standard and robot-assisted) have revolutionized the field of urologic surgery over the past quarter century and have established their role in the management of the entire spectrum of benign and malignant urologic diseases [1–3]. A growing body of evidence has demonstrated that these minimally invasive techniques allow quicker postoperative recovery for patients, ultimately improving their quality of life. On the other hand, the spread of laparoscopic techniques has resulted in unique complications specifically associated with their implementation [4–6]. Most urologic laparoscopic procedures are performed via the transperitoneal approach. However, the laparoscopic retroperitoneal access follows the same principles to exit the surgical field safely.

This chapter focuses on the technique and instrumentation needed to safely and effectively accomplish the final step of any laparoscopic or robotic urologic procedure, which has been referred to as "laparoscopic exit" [7]. This step can be divided into three key segments, each one important and each with specific challenges related to the unique conditions under which laparoscopy is conducted: specimen retrieval, incision closure, and drainage. Any shortcuts have a strong potential to convert a straightforward case into a formidable venture with unintended postoperative complications such as delayed bleeding, dehiscence, or a postoperative hernia, increasing patient morbidity.

The "laparoscopic exit" should follow a systematic, step-by-step approach (Figure 86.1) as described in the following sections.

## Specimen retrieval

Entrapment and extraction of surgical specimens are important steps that require specific laparoscopic skills and knowledge. Previous familiarity with materials and devices used during this step and knowledge of the specimen dimensions will ensure the safe removal of the surgical specimen, especially during oncological surgery to prevent tumor seeding in the extraction site [8, 9]. The retrieval site must be planned to optimize the cosmetic and pain-related outcomes.

### Retrieval devices

#### Commercially available devices

A wide variety of single-use retrieval devices are commercially available. All these devices feature sac permeability, resistance, stability, and easy handling. However, each one has specific characteristics, and the use of one over the others is mainly dictated by surgeon's preference as well as availability. These devices come in different sizes (5–15 mm), and the use of one size depends on the size of the specimen to be retrieved. In urology, a 10 mm bag is usually suitable for the laparoscopic partial nephrectomy, radical prostatectomy, adrenalectomy, or lymphadenectomy, whereas a larger 15 mm bag is needed for larger specimens retrieved during radical cystectomy or radical nephrectomy.

Retrieval devices can be divided into two categories:

- *Pure sacs* (Table 86.1) are primarily made of polyurethane and their closure involves a purse-string mechanism. Examples of this category include LapSac™, SimplyStrong™, Endobag™, and Trapbag™.

Specimen retrieval
• Use of retrieval devices
• Selection of extraction site
• Morcellation vs. intact specimen
Inspection
• Check hemostasis (lower insufflation)
• Rule out organ injuries
• Trocar removal under vision
Closure
• Port site fascial closure
• Skin closure
• Drainage

**Figure 86.1** Exit strategy in laparoscopic and robotic procedures: a step-by-step systematic approach.

**Table 86.1** Laparoscopic entrapment devices: simple bags.

| Name | Description |
|---|---|
| SimplyStrong™ (Genicon, Winter Park, FL, USA) | Nylon with polymer coating; monofilament cinch string without introducer; grab points to extract bag; radiopaque thread |
| Endobag™ (Covidien/ Medtronic) | 5 in × 8 in; supplied in a dispensing tube; 10–12 mm trocar |
| TrapBag™ (Karl Storz, Tuttlingen, Germany) | Transparent; insertion through a pusher; memory wire; self-opening; “fish trap” patented system |
| LapSac™ (Cook Medical, Bloomington, IN, USA) | Reinforced nylon with integral polyurethane inner coating and polypropylene drawstring; 10–12 mm trocar; not self-opening |

- *Sacs with plunger and opening/closing system* consist of a bag collapsed into a cylindrical tube (plunger) that is introduced through the trocar, allowing the deployment of the bag via an opening system. A purse-string mechanism allows the bag to close (Table 86.2). Examples of this category include GeniStrong™, Endopouch™, TRS™, Inzii™, and Endo Catch™.

Pure sacs were commonly used before the advent of devices with a plunger and pouches with mouth opening deployment capability. Placement of retrieval bags with plungers must be done under direct visualization to avoid injuries to the abdominal organs, ensure adequate opening of the bag, and verify complete entrapment of the surgical specimen with closure of the bag to prevent spillage or partial removal of the specimen.

**Table 86.2** Laparoscopic entrapment devices: bags with closing/opening system.

| Name | Description |
|---|---|
| GeniStrong™ (Genicon) | Nylon with polymer coating; transparent introducer; preloaded spring automatically opens bag upon deployment; flexible metal ring holding bag mouth open for specimen loading; in different sizes: small and medium for 10 mm trocar; large for 12 mm trocar; XL for 15 mm trocar; rigid plastic shaft for stability; indicator for bag orientation; radiopaque thread |
| Endopouch™ retriever (Ethicon) | One-handed deployment, bag opening maintained by a metallic ring, string with a slip knot enables closing the bag; 10 mm diameter; 4 in × 6 in size |
| Anchor Tissue Retrieval System™ (ConMed Corp., Utica, NY, USA) | Nylon material; automatic opening; different sizes for 10–15 mm trocars; multiple use in single patient |
| Inzii™ Retrieval System (Applied Medical, Rancho Santa Margarita, CA, USA) | Also in 5 mm size; allows multiple uses in a single patients |
| Endo Catch™ (Covidien/Medtronic) | 10 mm or 15 mm; polyurethane pouch |

### Homemade (low-cost) devices

Alternative “low-cost” solutions have been described to minimize costs, such as the use of sterile gloves and other materials, but the safety and efficiency of these devices have not been tested to ascertain industry guidelines and quality assurance [10].

## Morcellation

Morcellation is the mechanical fragmentation of an (entrapped) specimen into smaller pieces using a manual or morcellator technique. It is used to minimize the extraction site incision, optimizing cosmetic and pain-related outcomes.

Morcellation has been closely scrutinized in gynecology due to the risk of bag perforation and bowel injuries [11]. The other concern relates to the challenges faced by the pathologist in accurately staging and defining the surgical margins. The use of morcellation in urology has been limited and is mainly restricted to laparoscopic benign cases; it is performed under laparoscopic visualization. Furthermore, no advantage of morcellation (over intact specimen extraction) could be found in studies looking at postoperative recovery, wound-related complications, and surgery-related quality of life [12, 13].

### Extraction site: where and how?

Extraction of the intact specimen can be accomplished through different sites depending on the size of the specimen. Small specimens (prostate, lymph nodes, or adrenal gland) can be easily removed by extending a trocar site.

A larger specimen can present a more challenging scenario to the laparoscopic surgeon during procedures such as a radical nephrectomy. In this case, different access options can be considered (Figure 86.2):

- Port site extension or connecting two port site incisions (paramedian or lower quadrant)
- Umbilical
- Pfannenstiel incision
- Incising a previous abdominal scar
- Natural orifice (vaginal or rectum) extraction.

Factors to consider when choosing between these options are the patient's preference, the surgeon's experience, cosmetic result, and risk of related complications.

Many surgeons prefer an umbilical or periumbilical incision due to familiarity with the midline abdominal wall anatomy. In this case, the incision is made through the umbilical scar to optimize the cosmetic outcome. This method has been popularized with the recent adoption of laparoendoscopic single-site (LESS) surgery, where the entire procedure can be performed through a periumbilical incision [14].

Several investigators have reported the risk of complications associated with the extraction sites. Elashry et al. found a higher risk of hernia when using lower flank port connecting incision for specimen removal and suggested a midline or subcostal incision instead, especially when other risk factors (such as obesity) are present [15]. Bird et al. compared three different sites (umbilical, paramedian, and lower quadrant) and found that incisional hernias were more likely to occur in patients with high body mass index and/or paramedian extraction site [16].

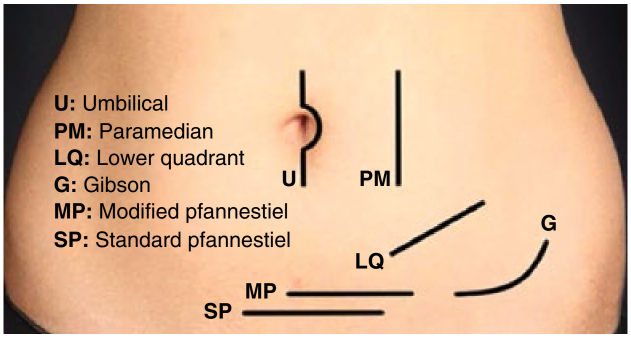

**Figure 86.2** Extraction sites for laparoscopic nephrectomy/nephrouretcerectomy.

The use of a Pfannenstiel incision after laparoscopic nephrectomy has been associated with potential advantages of better cosmesis and reduced pain [17]. During a transperitoneal laparoscopic nephrectomy, a Pfannenstiel incision can be used [18]. A skin incision is made about two fingerbreadths above the pubic symphysis. Instead of incising all the planes transversally along the same plane as originally described [18], just the skin can be incised transversally while the fascia is incised vertically, and the rectus muscles can be spread to enter the peritoneal cavity; this incision has been adopted for laparoscopic donor nephrectomy [19]. In the case of retroperitoneal nephrectomy, a "modified" Pfannenstiel incision can be used where the skin incision is biased toward the side of the nephrectomy, and after the anterior rectus fascia is exposed, a paramedian incision is made medial to the lateral border of the rectus muscle [20]. Then, after perforating the transversalis fascia, the Retzius (retroperitoneal) space is entered, and blunt finger dissection is used to gain access to the upper retroperitoneum [20]. In cases where this cannot be used (such as the presence of prior suprapubic incisions or in morbidly obese patients), a muscle-splitting extraperitoneal Gibson incision can be used [21]. The Pfannenstiel incision has also been described for LESS surgery [22]. Surgeons should be aware of the risk of ilioinguinal and iliohypogastric neuropathy with lower abdominal incisions [23].

In some female patients the transvaginal route can be performed by a laparoscopic transverse colpotomy made at the posterior fornix. After the specimen is extracted via the vagina, the posterior colpotomy is repaired transvaginally. The authors pointed out that vaginal extraction is indicated in patients with an intact uterus and a surgically unoperated pelvis where vaginal adhesions are not present [24, 25]. Vaginal extraction is not indicated (because of size concerns) for younger nulliparous females, those with atrophic vaginitis, vaginal infection, or when the specimen is too large. More recently, the transvaginal route has gained momentum with the introduction of natural orifice transluminal endoscopic surgery (NOTES) [26].

## Inspection

After completion of the laparoscopic procedure, careful examination of the surgical field is mandatory to rule out inadvertent injury to adjacent organs and to check the hemostasis. Intuitively, this is a fundamental step to minimize the risk of unrecognized intraoperative complications that can lead to significantly increased surgical morbidity, requiring more challenging management in the postoperative period.

Inadvertent organ injury can happen not only during the procedure itself but also very early when laparoscopic access is gained [27]. This more commonly occurs in special situations, such as when extensive adhesiolysis is needed [28]. Depending on the anatomical region where the surgery is performed, key structures need to be inspected. For right-sided renal procedures, the liver and duodenum should be examined and for left-sided procedures, the spleen and distal pancreas are frequently mobilized and retracted to access the kidney via transperitoneal laparoscopic approach [29, 30]. Diaphragmatic injuries can happen during dissection of the upper pole of the kidney but often changes in ventilation and oxygenation are observed requiring immediate action [31]. For pelvic procedures, attention should be paid to the small bowel, sigmoid colon, nerves, and vascular structures [32].

Careful inspection is also required to identify unrecognized bleeding, which can be tricky in the conditions under which laparoscopy is performed (i.e. with pneumoperitoneum). Although arterial bleeding is usually evident and easier to recognize, venous bleeding may be masked by abdominal pressure (~15 mmHg) during the laparoscopic procedure. Therefore, a key step of the “laparoscopic exit” is to lower the insufflation pressure to a minimum (<5 mmHg) and ensure proper hemostasis. In case of extraction of larger specimens requiring an extended incision, we recommend that the trocar site fascia defects should have a preplaced port site defect suture using a fascia closure device.

### Trocar removal

Trocars should always be removed under direct vision because inadvertent bleeding from the trocar sites can go unrecognized and create postoperative complications [33]. A bleeding trocar site should be managed by temporary tamponade with the trocar until the surgeon is ready to place a fascia suture to control the bleeding as described later in this chapter [34]. Bleeding at a trocar site can be challenging, especially in cases of morbidly obese patients where there is a thick subcutaneous layer. If the bleeding cannot be controlled endoscopically, the skin incision can be extended to have better exposure, identify the source of bleeding, and obtain proper control. A Foley catheter can also be introduced into the trocar site and used as a temporary pressure device by inflating the balloon to compress the vessel [35].

The last trocar to be removed should be the 10–12 mm trocar, leaving the optics inside the trocar without the valve cap so that insufflation gas and pressure can be removed from the intraperitoneal cavity with the assistance of the anesthesiologist (positive pressure with the ventilator). Then the trocar can be withdrawn while the fascia suture is pulled and the scope is removed, avoiding bowel herniation and entrapment.

## Port site fascial closure

Trocar site closure is performed to prevent possible port site hernias [36]. Shalhav et al. compared fascial nonclosure after using radially dilating trocars versus fascial closure after using cutting trocars and found no hernias after a mean follow-up of about five months [37]. Other investigators reported that ports <10 mm (8 mm robotic ports, 5 mm ports, and 3 mm mini-laparoscopic ports) do not require routine closure since the risk of hernia is minimal [38]. Nevertheless, case reports of herniation occurring even in 5 mm ports have been reported [39].

A variety of techniques and devices, either disposable (Figure 86.3) or reusable (Figure 86.4), have been used to obtain port site fascial closure. Maintenance of the pneumoperitoneum is of utmost importance to facilitate this step as it allows a safe distance to be kept between the abdominal wall and intra-abdominal viscera while endoscopic view can assist the closure [40].

In general, three different techniques can be used (Figure 86.5): intracorporeal manipulation under direct endoscopic vision, extracorporeal manipulation under direct endoscopic vision, and closure without direct endoscopic control. The use of one method over the other depends on surgeon’s preference and experience.

### Intracorporeal closure

Intracorporeal closure techniques have the advantage of maximizing safety by avoiding the risk of visceral injuries because they are performed under direct endoscopic

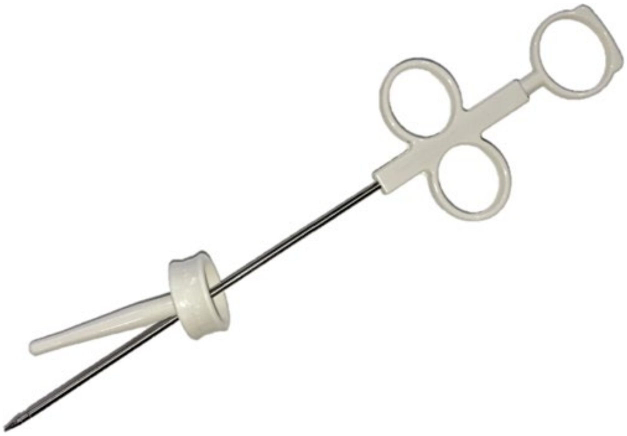

**Figure 86.3** Carter–Thomason laparoscopic port closure device: disposable.

vision (Figure 86.6). For this type of closure, various devices can be used [41]. The Maciol reusable suture needle set consists of a set of three needles: two suture introducers (one with a straight tip and one with a curved tip) and one suture retriever. An absorbable suture is placed percutaneously by using the introducer needle while the trocar remains in place. The retrieval needle is placed 180° from the initial suture passage and is used to grasp the end of the suture. A laparoscopic grasper is used to place the end of the suture into the retriever. Then, the trocar is removed and the fascia is pulled and closed by tying the suture. The Endo Close™ (Covidien/

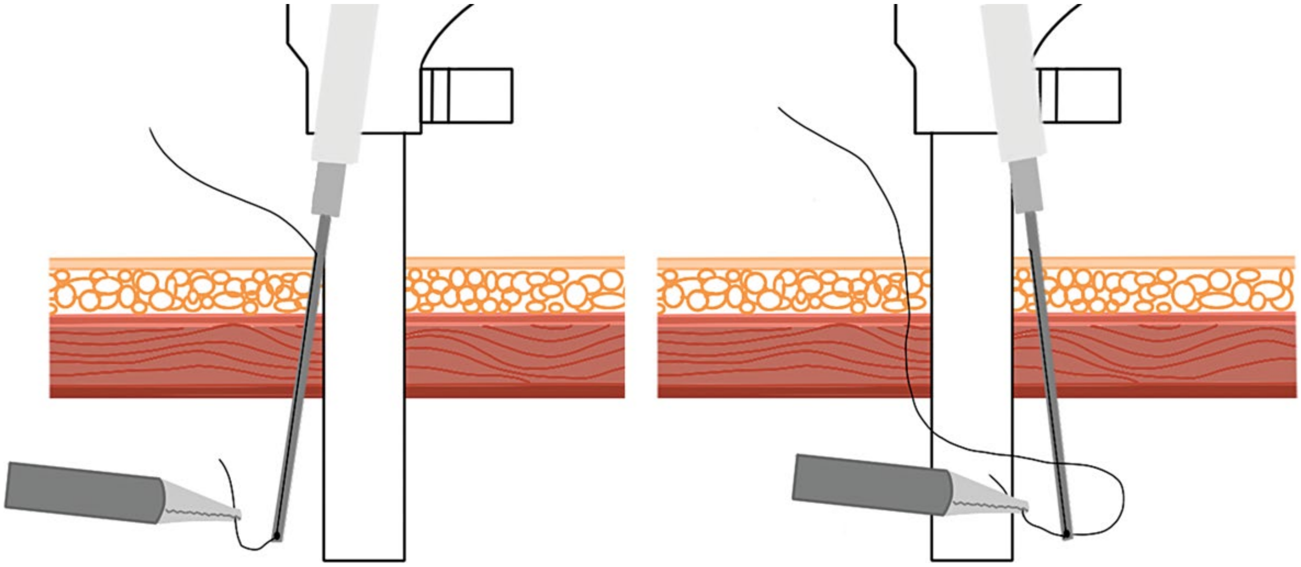

**Figure 86.6** Intracorporeal fascial closure techniques.

Medtronic, Minneapolis, MN, USA) is a spring-loaded disposable device which is loaded with a suture before being introduced into the abdomen between the trocar and the skin edge. The suture is released, and the device is placed 180° from the first passage. A laparoscopic grasper is needed to place the suture in the open notch of the device and the device is pulled together with the trocar so that the suture can be tied to close the fascia. The Gore™ Suture Passer (W.L. Gore & Associates, Inc., Flagstaff, AZ, USA) is a reusable device that works with a similar principle. While the trocar is maintained in place, the suture is loaded into the instrument, then passed on one side of the trocar, then released from the passer, and then grasped with a laparoscopic grasper. At this point, the passer device is removed and then inserted again on the opposite side of the trocar so that the suture is placed again back in the jaw of the passer, locked and pulled out so that the trocar can be removed and the suture tied down.

Low-cost methods without using any particular device have also been described to achieve intracorporeal closure. A venous catheter, a 15G spinal needle, or a 14G Angiocath needle have all been used to aid in fascial closure [40].

### Extracorporeal instruments

The most common technique used to close a trocar site is extracorporeal manipulation with endoscopic vision. A variety of disposable devices can be used for this purpose [40]. The Carter–Thomason CloseSure™ system (Cooper Surgical, Trumbull, CT, USA) consists of two parts: the pilot guide and the suture passer. Fascial closure can be obtained by four easy steps: the suture passer is used to punch the suture through the pilot guide, fascia, muscle, and peritoneum. On the opposite side, the suture passer is inserted through the wound so the suture can be pulled, encompassing the peritoneum, muscle, and fascia. The pilot guide is removed and the suture is tied. Other devices such as the Carter–Thomason II (Cooper Surgical, Trumbull, CT, USA), the Weck EFx™ (Teleflex Medical, Research Triangle Park, NC, USA), and the Weck® EFx Shield™ (Teleflex) are used with similar processes. In an in vitro cadaver trial, del Junco et al. found EFx to be superior in terms of time needed to complete defect closure, safety, and facility, and the Carter–Thomason to be better regarding maintenance of the pneumoperitoneum [42]. Others have described the use of a 2 mm trocar and sleeve (Miniport™, Covidien/Medtronic, Minneapolis, MN, USA) or a 5 mm trocar to obtain a safe and efficient port site closure [40].

### Standard technique

In this group of techniques, hand-sutured closures are performed, and several reusable devices can be used to help, such as the hook suture carrier [43], the Lowsley retractor [34], Reverdin needle [44], and Deschamps needle [45] (Figure 86.7). Most of the time there is no endoscopic view, and therefore a tactile sense should be used to aid in the closure. A "dual hemostat" technique, in which one hemostat is placed into the wound to lift the fascia and one to retract the overlying subcutaneous tissue, was suggested by Spalding et al. [46]. A standard technique of hand-sutured closure can be adopted where the skin is retracted; a Kocher clamp is used to grasp the

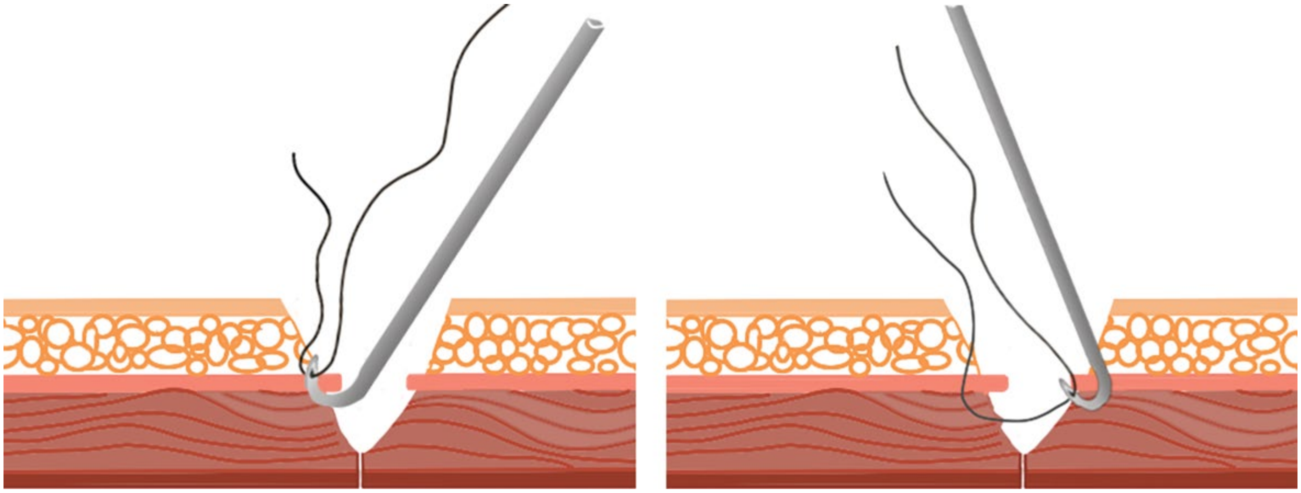

**Figure 86.7** Closure performed without endoscopic view: suture carrier.

fascia on either side and to lift it upward. A figure-of-eight suture is placed with endoscopic view preventing visceral injury [47]. This technique is easy in cases involving thin patients, but it becomes more challenging in cases involving large amounts of subcutaneous tissue.

## Skin closure

Before skin closure, the port site should be irrigated. Appropriate skin closure is a crucial step for any surgical procedure because obtaining cosmetically acceptable results translates into high patient satisfaction. Skin closure consists of a suture placed in the dermis to provide tensile strength and a suture in the epidermal layer to align the skin edges [48]. Port site skin closures are most commonly performed by running a subcuticular closure, with or without skin tape (steri-strip), as it enhances the cosmetic result and is useful for closing wounds with equal tissue thickness and in which virtually no tension exists. Usually, an absorbable suture (poliglecaprone 4-0 Monocryl®) can be used for this purpose.

### Skin adhesives

Fast-acting adhesives represent an alternative to formal skin closure. These adhesives dry quickly and can be used for laparoscopic port site wounds [49]. Two examples of commercially available adhesives are Dermabond® (2-octylcyanoacrylate; Ethicon, Inc., Somerville, NJ, USA) and Indermil® (*n*-butyl 2-cyanoacrylate; Covidien/Medtronic, Minneapolis, MN, USA). It is essential to obtain a dry surface with good edge-to-edge approximation before applying these glues. Cost remains a drawback on these materials when compared to traditional sutures. Several studies comparing adhesives to sutures for the closing of skin wounds have been reported, but there is insufficient evidence that port site wound closure technique by tissue adhesives is superior to traditional suture closure technique with regard to wound infection, wound dehiscence, and patient satisfaction [50].

## Drainage

Drainage after urologic laparoscopic and robotic procedures is used to allow prompt postoperative diagnosis of potential complications, which can vary depending on the procedure performed (Table 86.3). One should be aware that various drain-related complications are possible, such as hematoma, pain, and loss of a drain in the abdominal cavity. Therefore, the risks and benefits of using a drain should be considered after each procedure. In general, each surgeon has his or her preferences regarding drainage. Radical nephrectomy does not require drainage in most cases because potential postoperative bleeding can be identified by looking at clinical parameters such as vitals and urine output. Similarly, nephroureterectomy does not require drainage because the risk of urine leakage from the bladder opening is prevented by the use of a Foley catheter. A different scenario is presented by laparoscopic/robotic partial nephrectomy where there is a potential risk of both hemorrhage [51] (from the renorrhaphy site) and urine leakage [52, 53], which are both directly correlated to tumor complexity. On the other hand, recent evidence has suggested that a drain can be safely omitted in a majority of robotic partial nephrectomies because it seems to have minimal benefit [54–56].

**Table 86.3** When and why a drain is left in major urologic laparoscopic procedures.

| Procedure | Drainage | Rationale |
|---|---|---|
| Nephrectomy | Usually no | Only if high concern for bleeding |
| Partial nephrectomy | Yes | Identification of urine leak and hemorrhage from resection bed |
| Nephroureterectomy | Usually no | Urine leak from bladder prevented by Foley |
| Pyeloplasty | Yes | Early identification of urine leak |
| Adrenalectomy | Usually no | Only if high concern for bleeding |
| Lymphadenectomy | Yes | Risk of lymphocele, if extended dissection |
| Radical prostatectomy | Yes | Identification of urine leak |
| Radical cystectomy | Yes | Identification of urine leak; identification of dehiscence of bowel suture |

The use of a drain after minimally invasive radical prostatectomy helps to identify and manage urine leakage from the urethrovesical anastomosis. Risk factors for urine leakage have been identified (obesity, prostate size, previous prostatic surgery, difficult anastomosis, or anastomosis under tension) and drain output is a primary method of diagnosis [57]. On the other hand, watertight anastomosis verified intraoperatively does not require drainage [58].

Over the past five years, minimally invasive radical cystectomy has become popular. The adoption of robotic surgery has also facilitated the standardization of intracorporeal urinary diversions [59]. Radical cystectomy is a procedure that carries a high risk of complications even for experienced surgeons [60]. Complications include urine leakage (from the ureterovesical anastomosis as well as the urethra-neobladder anastomosis for orthotopic diversion), and bowel anastomosis leakage.

## Types of drains

Different types of drainage systems may be classified as closed systems, with or without suction, and open systems (Figure 86.8). The Jackson–Pratt® wound drain (Cardinal Health, Dublin, OH, USA) is a closed-suction silicone drain with a bulb (100 ml). The Hemovac® (Zimmer Surgical, Inc., Dover, OH, USA) and the Davol® (C.R. Bard, Inc., Covington, GA, USA) are larger, closed-suction drains (400 ml) that feature a collapsible disk shape. The Penrose drain is a passive drain made of soft latex that is open at both ends; it is rarely used for laparoscopic procedures. Closed-suction drains can

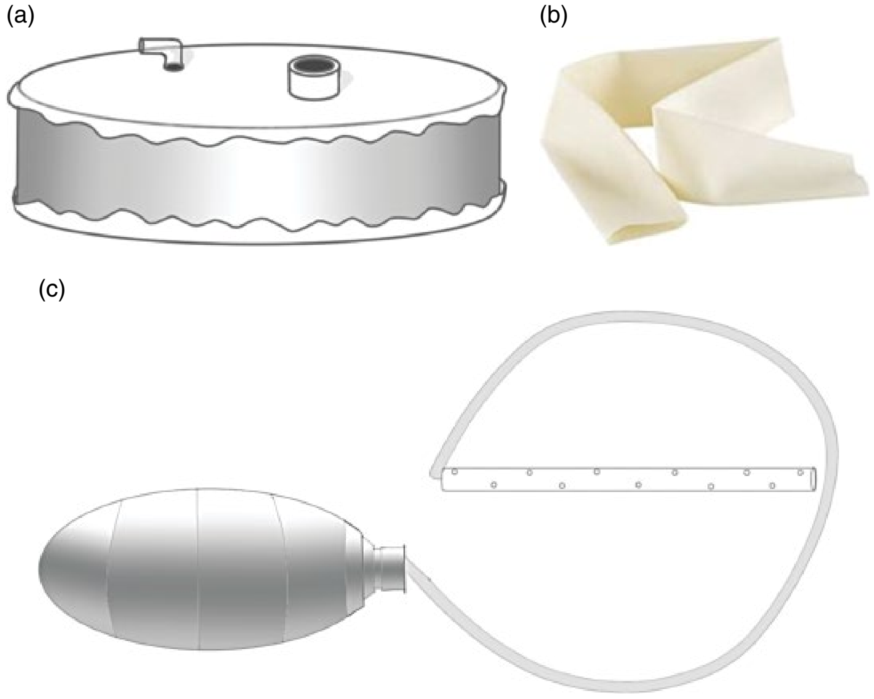

**Figure 86.8** Types of drains. (a) Hemovac; (b) Penrose drain; (c) Jackson–Pratt drain.

increase the risk of urinary fistula by creating continuous negative pressure.

### Technique of drain placement (see Videos 86.1 and 86.2)

Placement of a drain during a laparoscopic procedure is straightforward and can be done in various ways. The drain tube can be threaded into the intra-abdominal cavity through the desired port, and the distal end of the tube can be positioned at the desired location under endoscopic vision when the abdomen is still insufflated. In another method, the proximal end of the tube is threaded through a first port and out through a second access port to draw the distal end of the tube into the intra-abdominal cavity. Some tricks can be used to aid in drain placement. For example, one 5 or 10 mm port and the tip of a grasper (inserted through another port) can be aligned together so that the grasper is threaded inside the lumen of this port. By railroading, the port is gradually withdrawn while still holding the grasper tip inside so that the closed grasper jaws are brought out through the port site and the port is removed. At this point, the distal end of the drain is fed over one of the open jaws of the grasper. While holding the drain in the closed grasper, the drain is gently pulled into the intra-abdominal cavity and then positioned in the desired location under vision.

Once the drain is placed in the desired position, it is critical to secure it in place by placing a drain stitch, which is usually a nonabsorbable (silk or nylon) suture. During this step, the drain should be clamped to avoid leakage of $CO_2$ and maintain the pneumoperitoneum.

### Introduction

Although laparoscopy has decreased the morbidity related to many urologic procedures, the solutions to complications arising in the minimally invasive environment frequently have no direct open surgical counterpart. For example, laparoscopic access is often obtained through a variety of initially blind punctures where viscera and blood vessels are susceptible to unique injuries. The insufflated abdomen presents specific potential physiologic complications, complex instrumentation can malfunction catastrophically, and inadvertent injury can occur outside the laparoscope's field of view due to unobserved instrument gestures. Laparoscopy therefore requires a specialized knowledge base, and demands a unique set of troubleshooting skills. Whereas textbooks have been devoted to laparoscopic complications, this chapter will cover the main areas pertinent to the urologist in training, as well as for the practicing urologist wishing to broaden their knowledge.

Since urologic laparoscopy is no longer in its infancy and surgical complexity has increased, warnings and advice about complications from the dawn of laparoscopy may no longer be appropriate. For example, open conversion is less often required for the contemporary surgeon than it was in the past (in early series prior to 2000 conversion was as high as 2.1% [1]). Although the threshold to convert must remain low, and the window to address an evolving complication is short, the options and expertise to intervene without making an incision have expanded. The surgeon must exercise particular care during the learning period; multiple studies in the urologic [2, 3] and general surgical literature [4] have demonstrated an inverse relationship between surgeon experience and complication rates.

Complications in this chapter are organized by major category: (i) access, (ii) physiologic, (iii) patient positioning, (iv) end-organ (vascular, bowel, solid organ), (v) postoperative, and (vi) miscellaneous. Where appropriate, complications pertaining to specific urologic procedures will be highlighted. Since robotic techniques have essentially duplicated laparoscopic counterparts for all procedures, all complications discussed herein and their management are generalizable to robotic surgery. The classification schema proposed by Clavien–Dindo will not be specifically reviewed, but the reader is urged to review this separately [5].

### Access complications

Regardless of the method used to gain initial deliberate entry into the peritoneal (or retroperitoneal) cavity, access remains a significant source of morbidity and potential mortality. The incidence of any type of access injury ranges from 5 in 10 000 to 3 in 1000 [6]. In a recent literature review of 41 articles, including almost 700 000 procedures for which Veress needle access was used, 1575 (0.23%) injuries occurred [7]. The majority (92%) of these injuries were minor. Although the risk of access injury is low, it is not negligible, and a surgeon is statistically likely to encounter several over the course of a career.

The following access techniques are available:

- *Veress needle (closed entry)*, whereby a hollow needle with a retractable blunt tip is passed across the abdominal wall. Upon transperitoneal entry, the blunt cannula springs back into place, theoretically blunting the needle tip. Insufflation is then carried out through the needle.

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.
© 2019 John Wiley & Sons Ltd. Published 2019 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/smith/textbookofendourology

- *Hasson (open entry)*, whereby access is gained via a mini-laparotomy approach and all layers are entered sharply [8].
- *Optical trocar*, a camera-guided approach where the camera sits within the trocar's transparent conical-tipped obturator, and all layers of the abdominal wall can be seen as the trocar is advanced [9]. This technique can be employed alone in a desufflated abdomen or following initial insufflation via a closed (Veress) needle.
- Other techniques, less commonly used in urology, include radially expanding trocars and direct trocar insertion.

A 2008 Cochrane literature review comparing open and closed entry techniques found that there was insufficient evidence to recommend one technique over another [10]. No technique is foolproof. Experts acknowledge, however, that a prospective study powered to detect a meaningful difference would require thousands of patients and is unlikely to be organized. Generalized underreporting of complications further hampers attempts to define the true incidence of entry complications. However, a careful review of smaller studies reveals some take-home points. The incidence of vascular injury is probably higher with closed techniques [11]. Bowel injury is equally likely with open and closed entry techniques [12], but there may be a higher chance of immediate diagnosis with an open technique, since the injured bowel is directly visualized. Even so, delayed diagnosis of bowel injury has occurred following open access as well [13].

The nuances of safe access are highly subject to individual surgeon preference. As such, evidence-based literature only goes so far, and there is no substitute for hands-on bedside training. In our opinion, for instance, Veress needle safety checks, such as aspiration and saline drop, can provide valuable clues when performed correctly and in conjunction with verifying a low opening pressure (ideally $< 9$ mmHg). A published report on this matter, however, concluded that the ancillary needle checks provided little useful information apart from opening pressure [14]. The literature must be interpreted with caution in this arena, since the most important factor in gaining safe access is surgeon familiarity and mastery of a given approach.

Flexibility to use a different technique when called for is crucial. When the surgeon encounters difficulty gaining access by any approach, the advice to *change something* is prudent. A quote widely attributed to Einstein captures this concept: "The height of insanity is repeating the same thing over and over and expecting a different result." Stubborn repetition of the same maneuver invites complications. In a difficult access situation, careful reassessment of landmarks, checking for faulty equipment, and evaluating approach angles, can make all the difference. The trocar design must not create false reassurance, as even shielded trocars have not been shown to decrease access injuries. Also, be aware that in obese patients, reliable surface landmarks, such as the association between the umbilicus and aortic bifurcation, are lost.

The preventative guidelines in Box 87.1 are not data driven, but rather based on our experience. They are applicable for all types of laparoscopic access.

## Physiologic complications

Pneumoperitoneum is associated with potential complications and physiologic alterations both from its mechanical compressive effects on blood vessels and viscera, and

**Box 87.1 Preventative guidelines for laparoscopic access.**

1) Prior to skin incision, ensure that you have a working camera, insufflation, cautery, and laparoscopic suction.
2) Choose an entry site at a safe distance from prior scar, as underlying adhesions may be present.
3) With multiple prior abdominal surgeries, strongly consider open (Hasson) access.
4) If a Veress needle is chosen, decide a priori on the number of "attempts" you will allow before switching to an open access technique (we recommend three at most). Complications increase as attempts increase [11].
5) If you believe that elevating the abdominal wall is important, elevate the fascia (with a traction suture, Kocher clamp, or hand grasping and lifting the abdominal wall); do not elevate the skin only, as this will *increase* the distance to the peritoneal cavity.
6) Make sure Foley bladder decompression and orogastric tube stomach decompression have been instituted (especially in the pediatric population).
7) Ensure anesthesia has achieved complete muscle relaxation. A possible cause of high opening pressure (Veress access) other than preperitoneal needle placement is incomplete patient relaxation.
8) After the trocar has been placed, look in with the camera immediately. If vascular injury has occurred, the window for diagnosis and intervention is short. Do not waste precious time cleaning the camera lens prior to your first look inside.

by its potential entry into the bloodstream and subcutaneous tissues. Carbon dioxide is utilized because it is widely available, noncombustible, colorless, and readily absorbed. An unfortunate by-product of its favorable diffusion properties is the potential to decrease blood pH with prolonged absorption. Patients with severe pulmonary disease in whom the ability to counteract acidosis with hyperventilation is impaired may have a relative contraindication to laparoscopy [15], but this is rarely encountered clinically.

Although other pulmonary changes are best considered expected alterations rather than complications, they warrant mention nevertheless. Metabolic acidosis from hypercapnia can typically be measured in the form of expired $CO_2$. With mechanical ventilation, the clinical consequences are typically insignificant [16]. The mechanical compressive effects of pneumoperitoneum on the diaphragm causes increased intrathoracic pressure, increased peak airway pressure, and decreased vital capacity.

Hemodynamic effects of pneumoperitoneum are variable and difficult to generalize [16], but a prospective study by Meininger et al. thoroughly assessed this question by studying 10 patients undergoing robotic prostatectomy using a central venous catheter in place [17]. They were able to accurately measure cardiac output using thermodilution, cardiac index (CI), heart rate, mean arterial pressure (MAP), systemic vascular resistance (SVR), and central venous pressure (CVP), and correlate these with Trendelenburg position as well as pneumoperitoneum. The only hemodynamic parameter associated with Trendelenburg was an increase in CVP. Pneumoperitoneum only resulted in an increased MAP. Importantly, cardiac output was not affected either by Trendelenburg position or by pneumoperitoneum. The reader should note that other studies have demonstrated conflicting results in this arena.

Two important clinical scenarios are frequently encountered. First, the patient is found to have profound bradycardia as an initial response to peritoneal insufflation. The abdomen must be swiftly desufflated and anticholinergics administered. If the physiologic response occurs during a closed (Veress) entry technique, rapid desufflation is not immediately possible, as this can only be carried out after primary trocar placement. In this difficult scenario, the surgeon must proceed rapidly without placing the patient at risk from overly aggressive trocar insertion. Attention to safe trocar placement is well worth a few extra seconds of bradycardia.

Second, if an air embolus is suspected, the often cited Durant maneuver [18] is suggested to prevent the “air lock” from sitting in the right ventricular outflow tract. In the original study, animals that were positioned left side down had improved hemodynamics. In this position with the right side up, and furthermore in Trendelenburg, theoretically the air is prevented from entering the pulmonary outflow tract. A central venous catheter may be inserted to aspirate the air. Some authors have since pointed out that these effects have not been reliably reproduced in humans, and the position may be cumbersome and impractical in an emergency situation [19]. Nevertheless, the presentation of air embolus is dramatic, especially if Veress needle high-pressure insufflation directly into a major vessel is the cause. The patient develops sudden hypoxia, hypercarbia, and cardiovascular collapse.

The overall incidence of subcutaneous emphysema is 0.4–2.3% [20]. Subcutaneous emphysema is typically clinically insignificant and resolves without specific intervention. It may occur with initial preperitoneal Veress needle insufflation. Alternatively, a combination of a snug skin incision and loose fasciotomy around a trocar allows gradual development of ongoing subcutaneous emphysema during surgery. During lower tract laparoscopy, subcutaneous emphysema in the scrotum and penis is not a subtle finding, and should be manually decompressed at the conclusion of the case.

The presence of subcutaneous emphysema underscores the ability of pressurized gas to diffuse between body compartments [20]. Gas may similarly enter the pleural cavity, mediastinum, and pericardial space. Small collections of air in these spaces, without clinical instability, can typically be managed conservatively since $CO_2$ is readily absorbed.

## Complications of patient positioning

The surgeon often relies on gravity and patient positioning for adequate exposure during minimally invasive genitourinary procedures. Patient positioning, and at times prolonged operative times, predisposes the patient to four potentially painful and debilitating problems if precautions are not taken: neuropraxia/neuropathy, rhabdomyolysis, compartment syndrome, and pressure ulcers [15]. Complications in this arena are position- and therefore procedure-specific. In a large series of urologic laparoscopic procedures compiled from 15 centers and over 1600 cases, the overall incidence of neuropraxia was 2.7%, including rhabdomyolysis in 0.4% [21]. Risk factors included obesity, longer operative times (>5 hours), and advanced patient age. In a postoperative patient with oliguria and myalgias, clinical suspicion of rhabdomyolysis is paramount, creatinine kinase should be checked, and the patient should be alkalinized expeditiously.

For upper tract laparoscopy, with the patient flexed in flank position, the following maneuvers are important:

use of axillary roll, avoiding excessive flexion, and padding all pressure points. For lower tract surgery, with the patient supine with arms tucked and legs variably positioned per surgeon preference, hands should be in an anatomic position (thumbs up) and sheets to "tuck" arms must not be overly snug around the arm.

## End-organ complications

### Vascular injury

Bleeding complications account for a substantial portion of laparoscopic complications. For example, intraoperative and postoperative hemorrhage accounted for 40% of all perioperative complications in a single institution analysis of urologic laparoscopic procedures from 1997 to 2006 [22]. The overall incidence of vascular injury during urologic laparoscopy is in the range 0.4–1.7% [1, 2].

The most feared vascular injuries carrying the highest chance of mortality when injured are the great vessels and their immediate branches: aorta, vena cava, and iliac vessels. Mesenteric vascular injury can also be a source of major bleeding. The most common scenario is injury by initial blind Veress needle puncture. This may initially manifest as blood aspirated from the needle. Alternatively, vascular puncture from primary trocar insertion can occur. In either case, possible causes include incorrect angle of insertion and/or uncontrolled axial insertion force. In case of injury, if secondary trocars can be swiftly inserted, holding pressure at the bleeding site with a gauze sponge and laparoscopic grasper (unrolled gauze will fit through a 12 mm trocar) usually gives the surgeon time to assess the situation and, if required, proceed with laparotomy in a controlled fashion [23].

Depending on the bleeding severity and origin, the surgeon must decide whether to use thermal energy, clips, or suture ligatures. With massive hemorrhage, immediate laparotomy is often required. One has precious seconds to determine whether initial laparoscopic attempts at control are feasible or futile. A hand-assist port may be placed as an intermediary to open conversion. If open conversion is required, the laparoscope should be lifted up to the abdominal wall and rapid incision made directly over it. In such an emergency, the incision should be generous for maximal exposure. Compression of the bleeding site allows time for anesthesia to catch up with resuscitation, and allows surgeons with appropriate expertise, such as vascular surgery, to join the team.

The epigastric vessels are the most commonly injured minor blood vessels during trocar or Veress needle insertion [24], when these are placed laterally off midline (Figure 87.1). Using a Carter–Thomason wound closure device [25], sutures placed above and below the bleeding site are usually sufficient to control the bleeding.

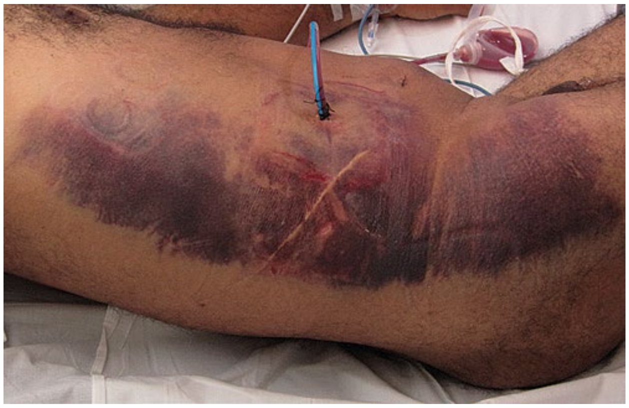

**Figure 87.1** Abdominal wall hematoma.

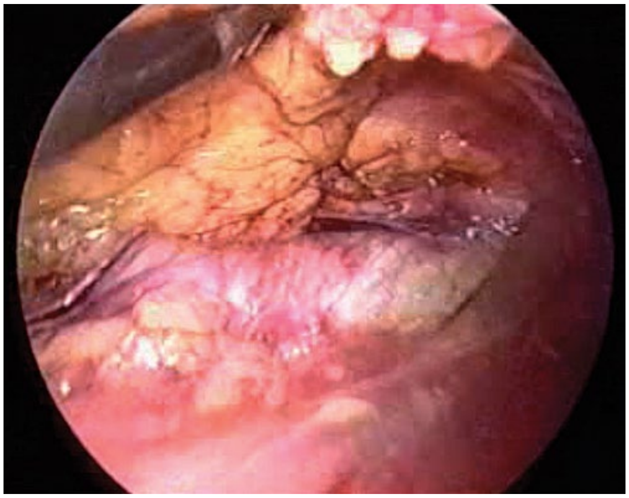

**Figure 87.2** Cava transected with vascular stapler, incorrectly identified as a renal vein.

A vascular complication specific to retroperitoneal laparoscopic right-sided nephrectomy is inadvertent ligation of the inferior vena cava (IVC) mistaken for the renal vein [26]. The cause is a lack of orientation to anatomic landmarks. During retroperitoneoscopic surgery, the psoas muscle must be maintained as the "surgical horizon" to maintain orientation. The renal vein must be verified to be heading towards the kidney (90° up, if the psoas horizon is maintained), with expected caliber. Most importantly, the renal vein–IVC junction above and below must be confirmed, as a prerequisite to renal vein ligation. If IVC transection is recognized (Figure 87.2), open vascular repair is suggested.

Bleeding is the main complication following partial nephrectomy (1.3–4.3%) [27]. One of the more common causes of intraoperative bleeding is an unclamped, unrecognized accessory renal artery. Great care must be

**Box 87.2 Bleeding set.**

- Two laparoscopic needle drivers
- Lapra-Ty and/or Weck clips, with appliers
- Laparoscopic Satinsky clamp
- Bulldog clamps, various sizes
- Surgicel absorbable hemostat
- Gauze sponge
- 2-0 Vicryl, SH needle, 10 cm long with Lapra-Ty at the end
- 2-0 Vicryl, CT-1 needle, 10 cm long with Lapra-Ty at the end
- Titanium clip applier, 5 and 10 mm (available in room, unopened)

taken both in evaluating preoperative axial imaging and during intraoperative hilar dissection to detect such variations. Delayed bleeding in the setting of hemodynamic stability can be addressed with selective embolization. In cases of hemodynamic instability, re-exploration is warranted. An attempt to ligate bleeding vessels is reasonable, but nephrectomy may be indicated if a single bleeding site is elusive or patient instability does not allow for renorrhaphy. In a large series of laparoscopic partial nephrectomy, reoperation was required in 2% and elective laparoscopic radical nephrectomy was performed in 0.5% [28]. When delayed bleeding manifests as hematuria, vascular fistula should be considered, and can be managed effectively with endovascular embolization.

As with any type of injury, prevention of vascular injury is best. A vascular injury "kit" should be prepared with each case (Box 87.2). Dissection should be performed in layers, widely completing more superficial layers before progressing deeper. Vascular injury of varying severity will occur, but poor exposure and "working in a hole" at the outset will severely limit the ability to control an injury. If staplers are used for vascular control, the stapler should be applied a few millimeters distally to provide a stump to grasp in case of catastrophic stapler malfunction [29].

## Bowel injury

The overall incidence of bowel injury in urologic laparoscopy (Figure 87.3) is approximately 0.2–0.7% [2, 3]. Since initial laparoscopic entry is one of the most common times for complications of any sort, a discussion of bowel complications is intimately related to access (see earlier). Rather than examining procedure-based datasets, a 2001 review examined international claims arising from access injuries from 1980 to 1999 and revealed that small bowel was the most commonly injured individual organ [13]. In this study, which included 594 injuries in 506 patients, claims were compiled both from legal suits made against a physician, and through mandatory device-related incidents reported to the US Food and Drug Administration (FDA). When multiple structures were injured, the most frequent combinations involved both a vascular structure and bowel. Of great practical concern was the observation that diagnosis was delayed greater than 24 hours for approximately half of all large and small bowel injuries.

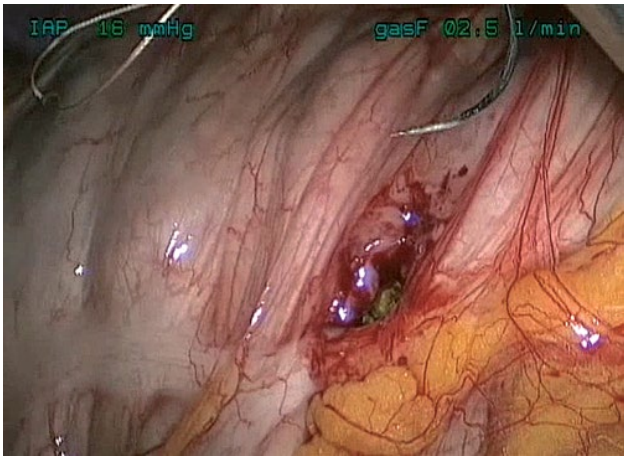

**Figure 87.3** Colon injury with primary trocar.

By far the most important take-home message regarding bowel injuries is that the injury may be subtle and early recognition is essential. In the study by Chandler et al., whereas small bowel injury conferred an odds ratio of 1.7 for patient mortality, greater than 24-hour delay in diagnosis increased the odds ratio to 3.7 [13]. Even more humbling is that because vascular injuries present so dramatically, delayed bowel injuries are more likely to cause death than major retroperitoneal vessel injury. In another injury-based database based on Medical Device Reports, the mortality rate in cases of delayed bowel injury was 21% [30].

When caused by a Veress needle puncture or trocar tip, laparoscopic repair of large or small bowel with intracorporeal suturing is readily accomplished. For large tears, or when significant adhesions preclude adequate assessment of the full extent of injury, open conversion and repair is recommended.

Trocar site herniation is another potential source of morbidity, occurring in approximately 1% of cases where bladed trocars are used [31] (Figures 87.4 and 87.5). Standard recommendations for port-site fascial closure include all trocar sites in children and trocar sites greater than 10 mm in adults [32]. The latter has been challenged, since newer dilating (nonbladed) trocars leave a much smaller fascial defect than the diameter of the trocar itself [33]. In our opinion, with modern trocar design there is seldom an indication for bladed disposable trocars as their use invites both vascular injury and postoperative herniation.

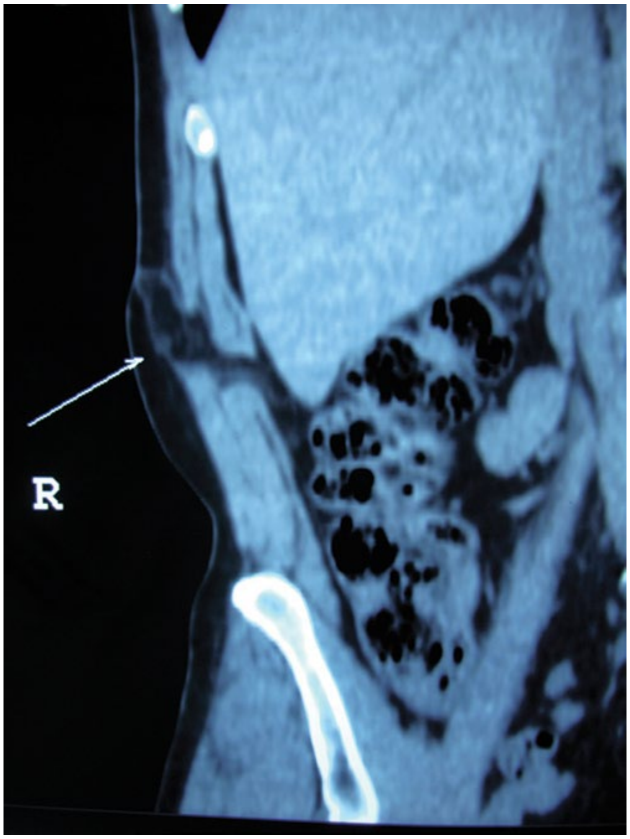

**Figure 87.4** Trocar site hernia.

Rectal injury, one of the most significant injuries during laparoscopic prostatectomy, occurs in approximately 0.5% of cases [34]. During the dissection, all areas of the rectum in relation to the posterior prostate surface are potentially at risk. Rectal injury can happen at the prostate base (incision too posterior through Denonvilliers' fascia), mid gland (wide neurovascular bundle resection), or apex. Preoperative bowel preparation allows for primary closure alone, since lack of gross fecal contamination may obviate the need for concomitant fecal diversion [35, 36]. Intraoperative diagnosis of even small injuries is best performed by instilling air per rectum with the pelvis filled with irrigant, whereby bubbling confirms rectal injury. Digital rectal examination or transrectal balloon placement may reveal larger injuries. Rectal injury may be further complicated by pelvic abscess (0.1%) or rectourinary fistula (0.1–1%) [37].

Predisposing factors for rectal injury include those that impair tissue integrity and/or obscure tissue planes. These include periprostatic fibrosis from multiple biopsies, prior prostate or rectal surgery, previous radiotherapy, locally advanced tumors, prior hormonal therapy, and prostatic infection. A non-nerve-sparing dissection with a wider dissection plane is also a risk factor, and the surgeon must therefore not be complacent in the belief that non-nerve sparing is an easier operative plane.

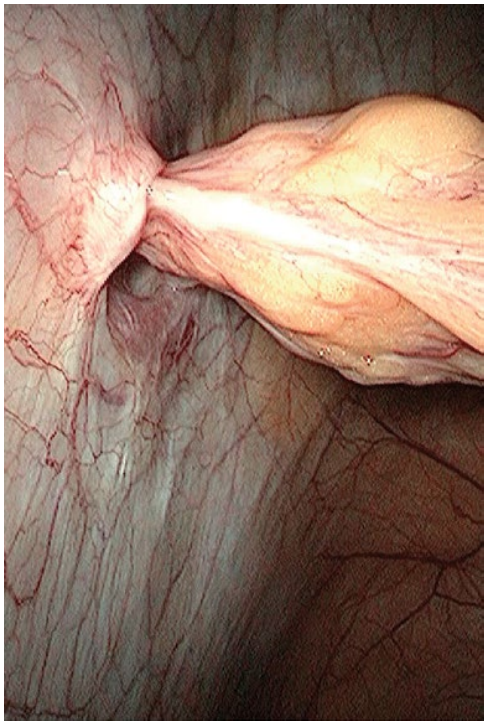

**Figure 87.5** Trocar site hernia at time of repair.

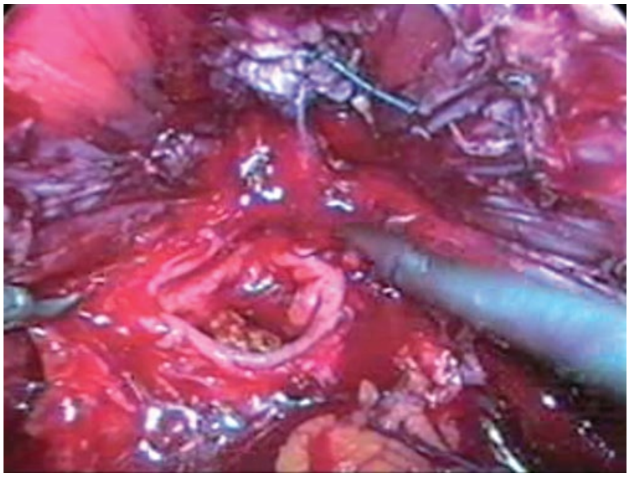

**Figure 87.6** Rectal injury during laparoscopic prostatectomy.

Rectal injury (Figure 87.6) can be managed laparoscopically or robotically without open conversion [38]. The defect should be closed primarily in at least two layers of nonabsorbable suture. The integrity of closure can be tested by instilling air in the rectum and watching for bubbles in a fluid-filled pelvis. By tacking the rectum laterally to the levator muscles, the rectal closure is drawn away from the urethrovesical anastomosis, minimizing the chance of fistula. A pedicle of omentum can be brought in over the rectal closure. Diverting colostomy or loop ileostomy should be considered in cases of tension at the rectal closure, massive fecal spillage, prior radiotherapy, and delay in diagnosis. A closed suction drain should be placed, and the patient covered with broad-spectrum antibiotics. A cystourethrogram must be performed prior to catheter removal to exclude urine leak, which may progress to rectourethral fistula if not recognized.

### Visceral injury

Of solid viscera, the liver and spleen are most at risk during right and left upper tract urologic laparoscopy, respectively. In one of the largest reviews of 2775 urologic laparoscopic procedures, the spleen was injured in 3.2% and the liver in 1.1% of cases [3]. In a meta-analysis broken down by procedure, the spleen was injured in 0.5% of radical nephrectomies and 1.3% of donor nephrectomies [39].

Most liver lacerations respond favorably to argon beam coagulation. For both liver and splenic lacerations, hemostatic adjuncts such as Floseal® (Baxter, Deerfield, IL, USA) and Surgicel® (Ethicon Biosurgery, Somerville, NJ, USA) are also useful. As a last resort, splenectomy should always be considered for severe bleeding or deep lacerations unlikely to resolve with standard maneuvers. The liver and spleen are injured similarly when retracted with an instrument tip rather than a broad surface (Figure 87.7). On the left side, complete mobilization of the spleen from the upper aspect of Gerota's fascia must be accomplished in order to avoid retraction injury.

One commonly encountered scenario is right-sided upper tract (renal or adrenal) surgery in a patient who has previously undergone cholecystectomy and in whom the liver is adherent to the posterior parietal peritoneum over Gerota's fascia. Rather than dissecting the liver directly, the liver should be mobilized with its adherent fascial layers by making an early incision into Gerota's fascia. By entering the retroperitoneum early and reflecting adherent tissue with the liver, injury may be avoided altogether.

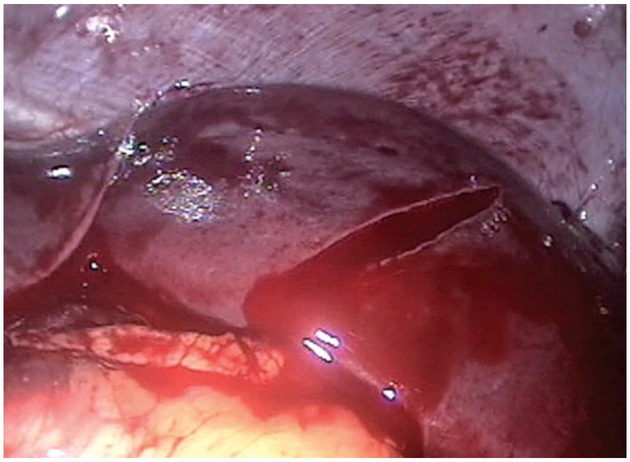

**Figure 87.7** Splenic laceration during specimen entrapment.

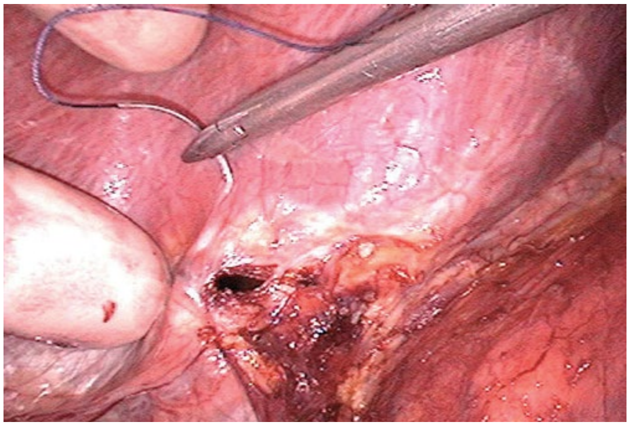

**Figure 87.8** Diaphragm injury.

The risk of diaphragm injury during urologic laparoscopy was 0.7% in one series [40]. This may occur deliberately as part of planned wide resection of a tumor invading the diaphragm, or inadvertently while dissecting in close proximity to it (Figure 87.8). The first indication that the pleura has been transgressed is a sudden billowing of the diaphragm into the abdominal cavity as the pneumoperitoneum rushes into the chest cavity [41]. Small injuries do not require open conversion to repair. A purse-string suture can be placed laparoscopically around a red rubber catheter exiting through a trocar and immersed in water. As anesthesia expands the lung, the air is evacuated and the suture is rapidly tied down as the catheter is withdrawn [40].

## Postoperative complications

Perioperative complications can be classified as either intraoperative or postoperative. In large series, postoperative complications account for approximately half of all complications [1]. The main complications of concern are bleeding (hemorrhage requiring reoperation or transfusion, operative site hematomas), urinoma, and wound complications (infection, hernia). Depending on the procedure, ileus and lymphocele formation are also of concern. The surgeon must be aware that "getting out" safely is as important as gaining access. In this regard, specific maneuvers should be part of standard practice.

Safe laparoscopic exit must include watching all trocar sites for active bleeding after trocar removal. For extirpative procedures requiring an extraction incision, reinsufflating and looking back after fascial closure provides useful information. Lack of bowel entrapment should be confirmed beneath the incision. If significant blood has accumulated during the period of desufflation, an exhaustive search for the bleeding site can obviate the need for re-exploration in the postoperative period. Significant postoperative bleeding presenting with hypotension, anemia, and abdominal distention is a clear sign of hemorrhage, but signs may be more subtle. If a surgical drain has been placed, the rate of filling and quality of fluid are important indicators of bleeding, but absence of blood in the drain does not exclude bleeding. Initial hemoglobin levels may be unchanged before serial measurements uncover anemia.

If surgical exploration is required for postoperative complications, relaparoscopy may be attempted in select cases [42, 43]. If a drain has been placed, it can be used to insufflate the abdomen. Open exploration is frequently required, but generalizations in this regard are difficult. For instance, re-exploration for bleeding following partial nephrectomy in a stable patient may be ideally suited to the laparoscopic approach as exposure of the renorrhaphy bed will be feasible. In contrast, bleeding following cystectomy and neobladder will be difficult laparoscopically as the urinary diversion and mesentery are now space-occupying structures obscuring view, and open exploration is warranted.

Urine leak in the postoperative period is pertinent after laparoscopy, pyeloplasty, and prostatectomy. Management of urine leak after pyeloplasty is initially conservative, as the majority will resolve following a period of encouraging maximal drainage (ureteral stent, Foley catheter, perirenal drain). A persistent vesicourethral anastomotic leak after laparoscopic radical prostatectomy is an uncommon complication with an unclear incidence (Figure 87.9). In one series, the incidence of leak requiring reoperation was 0.9–2.5% [42]. Most urinary leaks occur in the immediate postoperative period and are usually self-limiting with prolonged bladder drainage. Rarely, the surgeon encounters an anastomotic leak that does not resolve in the first two weeks.

Several conservative interventions are available for prolonged vesicourethral anastomotic leaks (Figure 87.10). These include prolonged retropubic and bladder drainage, passive rather than active drainage, advancing the drain away from the leak, bladder catheter traction, and bladder catheter needle-vented suction [44]. Particularly when the ureteral orifices are near the anastomosis, invasive techniques should be performed, including placing internalized or externalized ureteral stents. In case of ileus, abdominal pain, and/or urinoma, cystoscopy can provide information as to the degree of anastomotic separation. Laparoscopic re-exploration can be performed, the intra-abdominal urine evacuated, and the anastomosis either redone entirely or additional sutures placed.

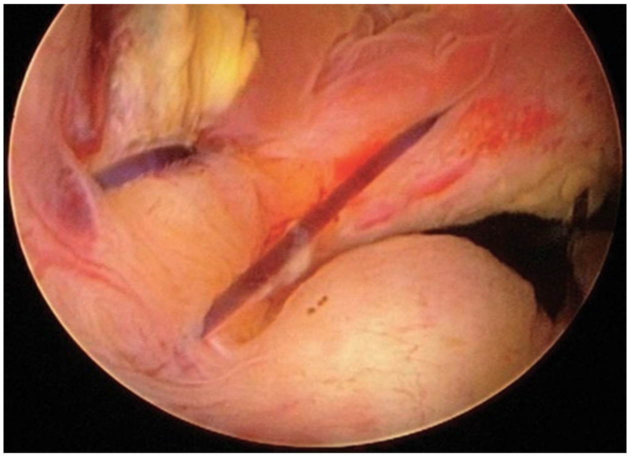

**Figure 87.9** Urine leak at urethrovesical anastomosis; anastomotic separation on cystoscopic view.

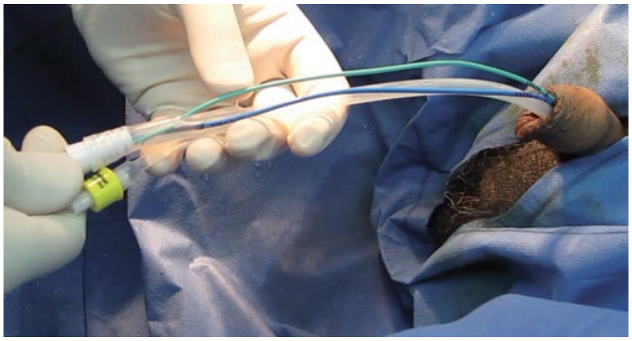

**Figure 87.10** Bilateral externalized ureteral catheters alongside Foley catheter for urethrovesical anastomotic leak.

## Miscellaneous complications

### Obturator nerve

The incidence of obturator nerve injury reported for open prostatectomy is 0.1–1%, and for minimally invasive prostatectomy 0.3% [45]. Given that the obturator nerve is fixed at either end, nerve mobilization to gain additional length is not feasible. As such, in the case of nerve loss, an interposition nerve graft may be necessary. If possible, an end-to-end reanastomosis with fine suture is ideal.

To avoid obturator nerve injury, a thorough understanding of normal anatomy is crucial, as this structure is one of the most reproducible, and its position scarcely varies in relation to bony landmarks. During lymphadenectomy, the lymph node packet should first be mobilized distally and reflected completely from the anterior surface of the nerve. When ligating the packet, it should be retracted medially, such that the full nerve is in view. Placing a clip parallel and medial to the course of the nerve will prevent inadvertent nerve injury.

## Ureteral injury

Ureteral injury is uncommon during laparoscopic upper tract surgery as its course is familiar to urologists. However, it is occasionally subject to injury during the learning curve of laparoscopic and robotic prostatectomy where its proximity to the seminal vesicle and bladder neck (ureteral orifices) are unexpected and unfamiliar. Ureteral injury was initially reported during the Montsouris posterior approach to the seminal vesical dissection, where the ureter was mistaken for the vas deferens [46]. In general, this is from errant dissection too far laterally. Double checking before ligating or dividing a tubular structure will prevent ureteral injury in this context. The other area of potential ureteral injury is the trigone. Care must be taken both during the posterior bladder neck dissection and during the anastomosis to identify the ureteral orifice. The incidence of ureteral injury during laparoscopic prostatectomy is approximately 0.8% [36, 47].

When ureteral injury is diagnosed intraoperatively, management depends on the injury type. Focal contusion without thermal energy may be managed conservatively with a ureteral stent alone. Suture repair and stenting of partial lacerations are appropriate. For complete transection, end-to-end anastomosis may be possible, but reimplantation is often a safer solution. When detection is delayed, repair is dictated by the location and extent of the injury, with the majority of injuries below the iliac vessels being managed with reimplantation. Percutaneous antegrade balloon dilatation may be suitable for delayed ureteric anastomotic stricture (Figure 87.11).

## Conclusions

Comprehensive preoperative planning and surgeon preparation can minimize or prevent complications from minimally invasive surgery. Particular care must be exercised during the learning curve, as multiple series have demonstrated that complications decrease with experience. The impact and sequelae of complications when they do occur can be minimized by rapid recognition and appropriate treatment. Humility is important; the first step in recognizing complications is being open to their occurrence. With this broad overview, the reader should be better placed to avoid complications, equipped to swiftly diagnose them, and more able to intervene should they occur.

## Introduction

With the increasing utilization of laparoscopy and robotics in urologic surgery over the past two decades, we have observed a shift in the type and frequency of surgical complications that can occur. Although minimally invasive surgery (MIS) provides great morbidity advantages when performed skillfully, the surgical approach differs greatly from the open alternatives. A surgeon transitioning to MIS must learn to recognize and treat a specific set of typical problems associated with this surgical method.

The management of surgical complications truly begins with the anticipation of a potential event. Without anticipation of these critical micro-events, complication prevention cannot occur. Preparing for surgery is the most important step in this process and will lay the groundwork for a safe, high-quality operation. Reviewing the medical history and relevant imaging immediately prior to surgery and identifying steps of the operation that may be particularly challenging for an individual patient are common sense but critical. Taking this disciplined approach, even to routine procedures highly familiar to the surgeon, will help avoid preventable complications.

Many of the techniques fundamental to complication avoidance in surgery have been developed and applied successfully by the aviation industry. The implementation of a presurgical checklist and timeout is familiar to most surgeons. These steps ritualize the presurgical review and improve communication among members of the operating room team. Their value has been well demonstrated in various studies [1–6], with the World Health Organization promoting its use in a global healthcare initiative [7, 8]. Beyond the checklist, a very impressive tool in modern aviation safety is called Crew Resource Management (CRM) [9]. The captain and crew of American Airways Flight 1549, who saved all passengers by landing in the Hudson River, referred to CRM as the key to successfully managing a potentially catastrophic complication. CRM aims to optimize the effort of the team in utilizing all resources and information available to a flight crew. A core component of CRM is communication, with the goal of facilitating cooperation. Pilots are encouraged to learn from errors, be willing to accept help from the crew, and use all available resources to make decisions. Many of these skills can be adapted for professional interactions in the operating room (OR) [10, 11]. The surgeon should be open-minded and pay attention to concerns brought forward by surgical assistants, anesthesiologists, or OR nurses. Likewise, the surgeon's instruction should be followed efficiently. Although implementation of such safety methodology has been shown to improve surgical outcomes, the current lack of standardized measurement tools limits possible conclusions [8].

Laparoscopy and robotic-assisted surgery have critically altered the interaction in the OR between the surgeon and other team members. On the positive side, the situation awareness of all team members is improved as everyone can see the surgical field on the video monitor and follow the progress of the operation. Conversely, a robotic procedure poses a unique challenge as the surgeon is not physically present at the bedside and has to rely on continuous feedback from the assistant. Without effective communication by vigilant bedside personnel, the surgeon may be completely unaware of a potentially dangerous evolving situation while his or her head is buried in the robotic console. Alas, even a highly experienced operating robotic surgeon can no longer single-handedly

monitor and control all activity at the operative field. This distributes some of the responsibility for identifying and preventing intraoperative complications onto the shoulders of potentially less experienced or knowledgeable OR staff, possibly increasing risk.

If a complication does occur in the OR, there is great value in providing a debriefing afterwards with all the team members involved. Direct feedback will help prevent avoidable mistakes in the future. Likewise, regular reporting of complications in a morbidity and mortality conference provides an opportunity for valuable peer review and education, which may decrease future complication rates.

## Pneumoperitoneum – considerations and complications

The insufflation of $CO_2$ for the maintenance of a pneumoperitoneum or inflated retroperitoneal space is generally performed at a pressure of 15 mmHg. At the initiation of pneumoperitoneum, severe bradycardia can occasionally be observed and should be anticipated by the anesthesia staff. Bradycardia may occur regardless of the patient's age and health status and is most likely an effect of a vagal stimulation caused by peritoneal stretch and irritation [12]. This can be seen more commonly during rapid abdominal insufflation through a large-bore trocar. Prompt desufflation of the abdomen combined with anticholinergic agents will resolve this in most cases, although in rare circumstances this phenomenon can lead to arrhythmias and cardiac arrest [12, 13]. The safest approach is to insufflate slowly at a low flow rate to a pressure of 12–15 mmHg. We also routinely notify the anesthesiologist verbally at the onset of insufflation, communicate actively during this phase concerning the patient's heart rate, and respond rapidly with desufflation if significant bradycardia develops. If the patient stabilizes swiftly and the anesthesiologist can rule out other potential causes of bradyarrhythmia, the case can generally be resumed without further restrictions.

$CO_2$ embolus is a rare but potentially lethal complication of peritoneal or retroperitoneal insufflation. Both the laparoscopic surgeon and anesthesia staff must maintain a low threshold to suspect $CO_2$ embolus if problems develop with intraoperative hemodynamics and/or oxygenation. Although $CO_2$ embolus can occur at any point in a laparoscopic procedure, the period of initial abdominal insufflation is a high-risk step. Malposition of either a Veress needle or primary trocar into a vessel or parenchymal organ can result in $CO_2$ embolus. The risk can be mitigated by using an optical trocar for initial access and by utilizing good Veress needle technique. In particular, aspiration from the Veress needle prior to insufflation is critical to assure that the needle tip does not lie within a vessel with attendant blood return. The incidence of $CO_2$ embolism during laparoscopy is exceedingly low but can have a fatal outcome with a reported mortality of 28% [14]. Clinical symptoms include systemic hypotension, dyspnea, cyanosis, tachycardia or bradycardia, arrhythmia or asystole [15]. Treatment entails desufflation, ventilation with 100% oxygen, head-down and left lateral decubitus (Durant's) position. In severe cases, an attempt to aspirate gas bubbles from the right atrium through a central line may be indicated.

Laparoscopic and robotic surgery are regularly performed with $CO_2$ insufflation pressures of 12–15 mmHg. However, elevation of the insufflation pressure to 20 mmHg is a common response to venous bleeding during a procedure. This increase in pressure can be remarkably effective in controlling bleeding and facilitating visualization. An increased insufflation pressure does have the potential to worsen venous return, renal blood flow, cardiac output and myocardial function, restrict diaphragmatic excursion, and increase $CO_2$ absorption, leading to hypercapnia and metabolic acidosis [16, 17]. Metabolic acidosis is compensated through hyperventilation and elimination of $CO_2$ through the lungs as well as by recruitment of endogenous buffer systems. Patients with limited pulmonary reserve will have less capacity to compensate for prolonged or high-pressure insufflation and need to be closely monitored for their reduced ability to eliminate excessive $CO_2$. Some authors have documented the safety of performing laparoscopic surgery under prolonged insufflation pressures of 20 mmHg in patients with normal pulmonary function [18]. It is important to recognize that traditional insufflators allow substantial fluctuation in abdominal pressure throughout surgery in response to leaks, suctioning, and instrument exchanges. More sophisticated modern insufflation systems, such as the AirSeal® device (Conmed, Utica, NY, USA), hold a very steady insufflation pressure at whatever value is selected and can withstand continuous suctioning without dropping pressure. Therefore, prolonged pressure at 20 mmHg using an AirSeal may be significantly more disruptive to normal hemodynamics, oxygenation, and acid–base balance than standard insufflation. We recommend elevating insufflation pressure to 20 mmHg as needed for bleeding but making a conscious effort to return to pressures of 12–15 mmHg as soon as it is feasible to do so during the case.

Abdominal insufflation can result in impaired renal function and low urine output during a laparoscopic procedure. These effects are believed to result from increased intra-abdominal pressure as well as hormonal changes from activation of the renin–angiotensin–aldosterone system [19]. Hemodynamic changes have a direct effect on parenchymal microperfusion and can lead to acute tubular necrosis and reduced glomerular filtration rate [20, 21]. Although these effects usually do not impair long-term renal function, patients with underlying chronic kidney disease may experience more significant transiently reduced urine output. Individual cases of irreversible kidney damage have been reported but these are relatively rare events [22]. Decreased urine output during insufflation should be anticipated and anesthesia staff should avoid overaggressive fluid resuscitation, which can lead to fluid overload and pulmonary complications [23].

The specific parameters of abdominal insufflation may also influence the degree of postoperative pain following laparoscopic surgery. Lower insufflation pressures have been clearly associated with decreased postoperative shoulder pain after laparoscopic cholecystectomy [24, 25]. Likewise, a prospective randomized trial demonstrated improved postoperative pain after laparoscopic gynecologic surgery when insufflation pressures were kept to 8 mmHg as compared to 12 or 15 mmHg [26]. In summary, we recommend keeping the duration of abdominal insufflation as brief and the pressure as low as possible for adequate surgical visualization to minimize the risk of intraoperative and postoperative sequelae.

## Patient positioning – considerations to prevent complications

Patient positioning must meet several requirements. The first, and most critical, consideration is assuring patient safety. The patient should be secured adequately to the table and all bony prominences and potential pressure points should be well padded. These considerations are especially critical in obese patients. Initial abdominal laparoscopic access often occurs in the supine position and the bed will often need to be moved prior to robot docking (i.e. tipped to the side). Testing the stability of the patient during bed movement is an important step before surgical draping. The anesthesia team must also have access to invasive lines and noninvasive monitoring sites (such as a blood pressure cuff) to allow troubleshooting during intraoperative care.

The second consideration in positioning is to provide acceptable access to the operative field for the surgeon so that the procedure can progress appropriately. The limited operating envelope of the da Vinci™ S and Si systems (Intuitive Surgical, Inc., Sunnyvale, CA, USA) constrains some of these choices for individual procedures unless redocking is planned. Patient positioning should take into account the docking path and position of the robot. The da Vinci Xi system provides substantially more flexibility in defining the operating envelope, allowing all four quadrants of the abdomen to be accessed from a single docking position. Likewise, potential conflicts of the robotic arms outside the patient should be factored into both patient and port positioning. These options may be limited in very thin patients or those of small stature. Even for laparoscopic procedures without robotic assistance, positioning the patient such that gravity can act to retract bowel is generally advantageous. This often means modified flank position for kidney cases and lithotomy with Trendelenburg position for pelvic cases. In all cases, the possibility of conversion to open surgery should be considered in positioning, particularly early in a minimally invasive surgeon's learning curve.

We position our laparoscopic and robotic kidney cases in a modified flank position (lateral decubitus) (Figure 88.1a). The side of the surgical site is elevated (left kidney–left side up) and the patient rests on a gel

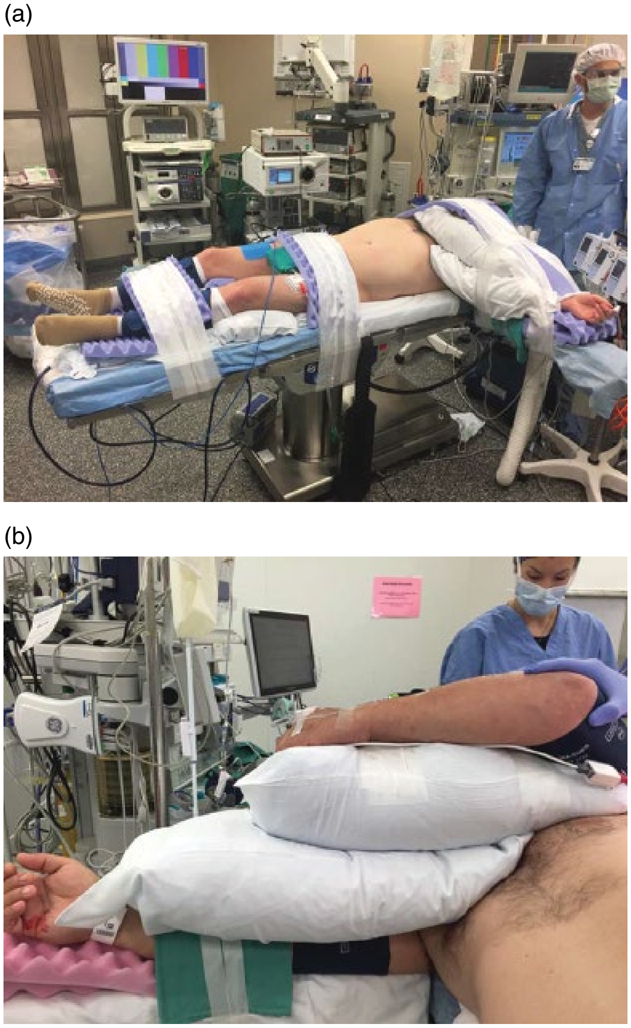

**Figure 88.1** (a, b) Example of patient positioning for laparoscopic and robotic renal surgery.

roll supporting the shoulders and the hip. The ipsilateral arm is brought over the contralateral side and is supported by pillows (Figure 88.1b) to pad all possible pressure points while avoiding overextension at the shoulder or elbow joints. Some surgeons prefer to place the ipsilateral arm along the patient's side to minimize potential contact with the cephelad robotic arm when working low in the retroperitoneum. The skin is covered with surgical foam and the patient is secured to the table with 3-inch (7.5 cm) silk surgical tape at the level of shoulders, hips and feet. We always test the position of the patient by turning the table sideways before the surgical skin preparation. For obese patients, we prefer to use extra tape and padding at the level of the hips and shoulders. Testing of the secure position prior to applying the drapes can help to reveal any weak points.

Patient positioning for pelvic surgery with the da Vinci S or Si systems requires Trendelenburg with the head down (30–40°) and the legs in lithotomy position. Since the da Vinci Xi system allows the arms to pivot on an overhanging boom, lithotomy position can be omitted for pelvic procedures with this system. To prevent the patient from shifting, the arms are usually secured on the sides with or without metal or plastic sleds. We use surgical foam and tape across the chest to prevent shifting toward the head. Custom-made support systems are available, providing additional support of the shoulders and holding the body in place (TrenGuard™, Pink Pad™) without tape across the chest. For obese patients undergoing pelvic surgery, assuring that the patient can be adequately ventilated when in steep Trendelenburg position should be confirmed with the anesthesia team prior to skin incision.

## Nerve injuries

The most common complications in laparoscopy are vascular, bowel, or adjacent organ injuries but peripheral nerve injuries related to positioning can have a substantial impact on postoperative quality of life. Nerve injuries result in up to 16% of anesthesia-related malpractice claims [27]. A recent analysis of >380,000 anesthesia cases across all surgical specialties revealed only 112 cases of true perioperative nerve injury (0.03%) but 13% of the detected injuries occurred during urologic surgery [28, 29]. Moreover, a review of 2775 urologic laparoscopic cases reported postoperative neuromuscular pain in 5.4% of patients [30]. Knowledge of the most sensitive pressure points can help to reduce the incidence of these type of injuries. The most common injuries arise from overstretching the brachial plexus, or compression of the peroneal or ulnar nerves.

## Rhabdomyolysis

Careful padding is also warranted to prevent postoperative rhabdomyolysis, a pressure-induced tissue injury leading to necrosis of muscle cells. Multiple factors associated with rhabdomyolysis, including hypovolemia, myoglobinuria, and metabolic acidosis, may cause acute kidney injury or renal failure [31]. Rhabdomyolysis is a relatively rare complication of urologic surgery. A recent outcome analysis reported only 870 events out of more than one million urologic cases [32]. However, a known risk factor for rhabdomyolysis is prolonged operative time [33]. This can be a significant risk in laparoscopic and robotic cases early in a surgeon's learning curve. The incidence of rhabdomyolysis in urologic laparoscopic cases has been reported to be as high as 1% [33, 34]. Immediate postoperative muscular pain, particularly in the buttock, hip, or flank should raise concern for potential rhabdomyolysis. Treatment consists of aggressive hydration and diuresis. Hemodynamic support and temporary dialysis may be required in more severe cases.

## Extremity compartment syndrome

Compartment syndrome of an extremity is increased pressure within a closed fascial compartment resulting in perfusion compromise and tissue injury [35]. This most frequently occurs in the trauma setting but can be diagnosed after surgery. In the setting of urologic procedures, compartment syndrome much more commonly involves the lower extremities. The terminology for cases in the lower limb is "well leg compartment syndrome" (WLCS) and will typically occur after prolonged surgery in the lithotomy position. Modifiable factors including heel support, modified lithotomy, avoidance of Trendelenburg and ankle dorsiflexion, as well as the use of intermittent compression devices may reduce the incidence. Extremity compartment syndrome is a clinical diagnosis and should be considered in cases of severe leg pain, lower limb swelling, plantar hypoesthesia, absence of pulse, and pallor. Confirmation of compartment pressures can be performed using a needle inserted into the compartment and connected to a pressure transducer [36, 37]. The treatment is immediate surgical decompression with fasciotomy.

## Infectious complications

The risk of urinary tract infection following laparoscopic surgery should not exceed that following open surgery. Clearly documenting a negative urine culture prior to any procedure in which the urinary tract will be violated is appropriate surgical practice. For laparoscopic nephrectomy, the rate of postoperative urinary tract infection has been reported to be 1.4% [38]. Even though some laparoscopic procedures may have significantly longer operative times than their open equivalents, this does not appear to result in an increased risk of sepsis, pneumonia, or surgical site infection [38].

## Thromboembolic complications

Thromboembolic complications, including deep venous thrombosis and pulmonary embolus, are some of the most common complications occurring after major surgery. A full description of risk mitigation and management of these complications is outside the scope of this chapter and the reader is referred to detailed recent reviews on this topic [39–42]. Several lines of evidence suggest that thromboembolic complications are less common in minimally invasive urologic, colorectal, and gynecologic procedures as compared to their open counterparts [43–45]. This is despite longer operative times and the negative influence of pneumoperitoneum on venous return for laparoscopic procedures.

## Intraoperative surgical complications

### Vascular injuries and intraoperative bleeding (see Video 88.1)

The most common type of intraoperative complication in urologic laparoscopic surgery is vascular injury, which has been reported to occur in 1.7–1.9% of cases [30, 46]. Urologic procedures in the retroperitoneum and the pelvis require identification, dissection, and preservation of major vessels including the aorta, vena cava, renal arteries and veins, superior mesenteric artery, inferior mesenteric artery, and iliac arteries and veins. The frequency of vascular injuries during urologic surgery differs from gynecologic surgery, when the most common vascular injuries occur during trocar insertion [47, 48]. Placement of trocars into a desufflated abdomen is strongly discouraged and has been associated with serious vascular injuries [49, 50]. During closed insufflation, placement of a Veress needle should not be limited only to the umbilicus. However, the surgeon should be aware of which structures are at risk for injury when placing the needle elsewhere in the abdomen (Figure 88.2).

The most effective way to avoid injury to major vessels is to anticipate the micro-events that lead to these complications in advance. One critical step is a thorough review of the relevant imaging preoperatively to identify any vascular anomalies and establish the relationship of the pathology in question to vascular structures. Early in a surgeon's experience, the use of multi-plane reconstructions and CT-angiograms may aid in defining this anatomy.

For nephrectomy procedures, prior knowledge of the number of arteries and veins serving the kidney facilitates a safe procedure. For retroperitoneal surgery on the left side, critical anatomic factors to anticipate include the presence of a large lumbar vein behind the renal artery, the location of the adrenal vein and the presence or absence of a retroaortic renal vein component. (Figure 88.3) The surgeon also needs to recognize the often intimate relationship of the superior mesenteric artery to the renal hilum to prevent a catastrophic complication [51]. On the right side, the junctions of the gonadal and adrenal veins to the vena cava are weak points that should be treated with caution. In pelvic surgery, the iliac vessels and branches are the primary source of major bleeding. Laparoscopic and robotic surgery provide less tactile feedback to aid in dissection, so these approaches demand the surgeon to maintain proper orientation and use visual cues to identify and preserve major vessels [52]. This is particularly critical in robotic cases where shifting orientation by 90° requires only a twist of the surgeon's wrists and may go unrecognized by both the console surgeon and bedside assistant. The robotic arms are also very strong and can inadvertently avulse major vessels if not monitored visually by the console surgeon [53]. In the case of a large renal mass, parasitic vessels due to neoplastic angiogenesis should be taken into consideration as well as the presence of regional lymphadenopathy that may limit safe access to the hilar vessels. In rare cases with bulky retroperitoneal lymphadenopathy, presurgical embolization of the renal artery may be advantageous [54–56]. Finally, for complex cases requiring vena caval thrombectomy, anatomy and the urologic surgeon's experience level should determine whether preoperative vascular or cardiothoracic surgery consultation is indicated. It is important to recognize that vascular surgeons facile with laparoscopic or robotic surgery are uncommon so their involvement may require open conversion at many institutions.

It makes sense to differentiate between two types of vascular injuries: (i) those intraoperative injuries that are immediately recognized and definitively dealt with during surgery; and (ii) unrecognized injuries that result in bleeding requiring blood transfusion, surgical exploration, or endovascular intervention in the postoperative period. A single institutional analysis from the Cleveland Clinic in 2007 reported intraoperative hemorrhage in 2.3% and postoperative bleeding events in 2.7% of 1867 laparoscopic oncologic cases [57]. Access-related vascular

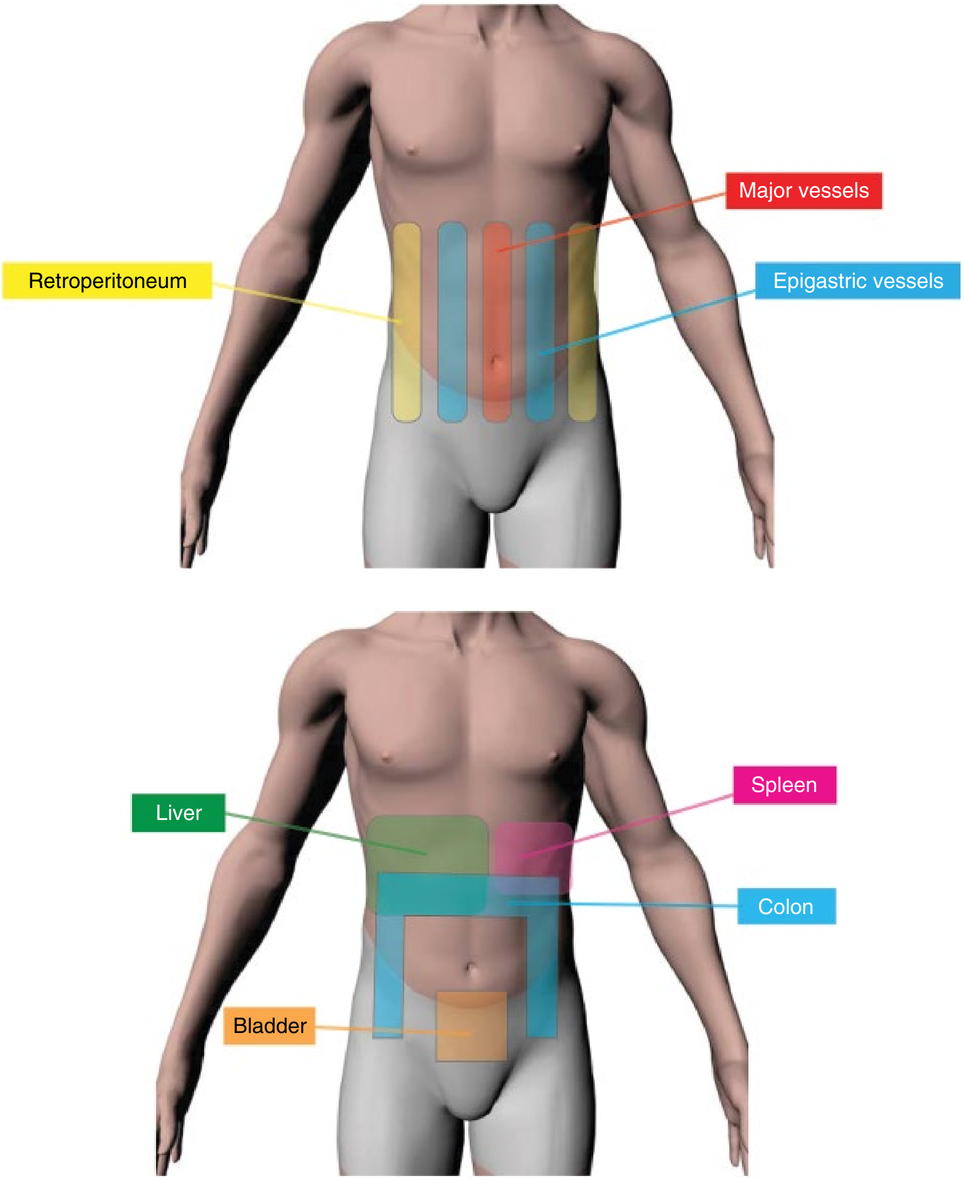

**Figure 88.2** Structures at risk during placement of a Veress needle for insufflation throughout the abdomen.

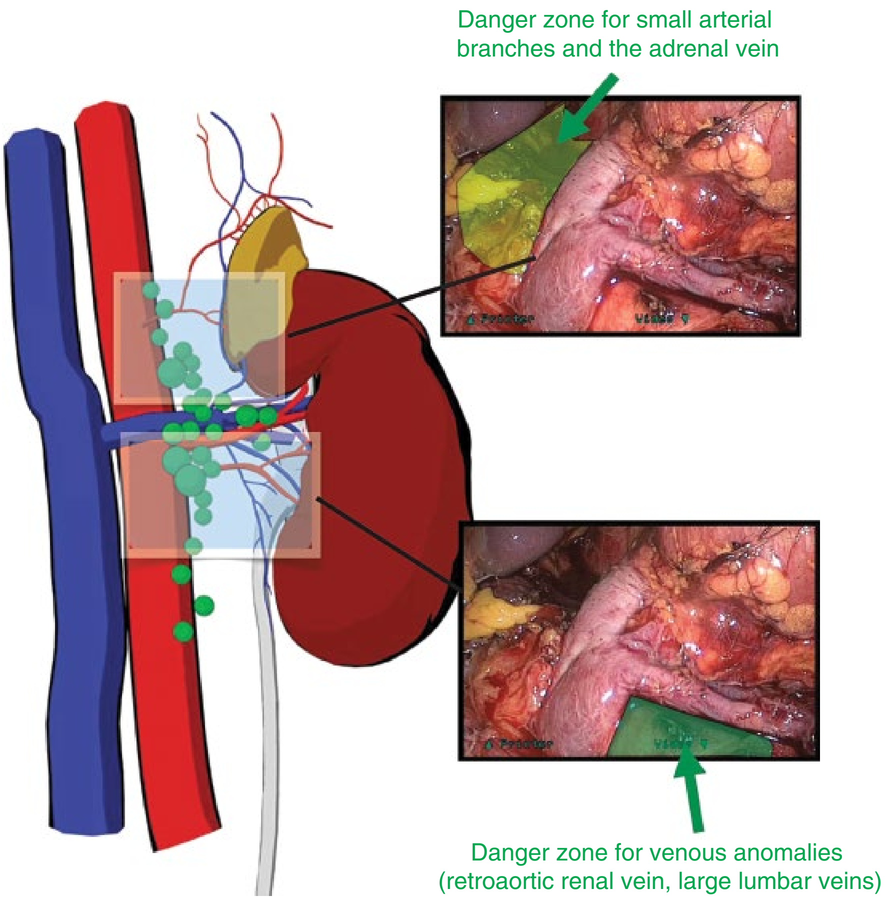
injuries most often involve the epigastric arteries or superficial vessels of the abdominal wall [58].

The minimally invasive surgeon should have a regimented plan in place to address bleeding during laparoscopic and robotic surgery. This process can be broken down into two phases: an initial "damage control" phase and a subsequent "definitive control" phase (Figure 88.4). During the damage control phase, the surgeon must rapidly assess (i) the scale of the bleeding; (ii) whether it is of arterial or venous origin; (iii) whether it can be temporarily controlled with local pressure; and (iv) whether definitive control will likely outmatch the surgeon's minimally invasive skill set and require open conversion. The first move in a moment of brisk bleeding should always be to apply pressure. This can be achieved by either grasping the vessel or stump involved or by applying pressure with a quickly inserted gauze (either an opened 4 × 4 sponge or a thin-profiled laparotomy pad designed to pass through a 12 mm trocar). The laparoscopic suction device is also very useful in safely exerting pressure. The vast majority of venous vascular injuries can be temporarily controlled with pressure and do not require rapid open conversion. This is a much wiser course of action than firing multiple clips in a semi-blind fashion as these clips may significantly compromise later attempts at definitive control if they are not immediately effective. Next the insufflation pressure should be raised to 20 mmHg. This will help to reduce most venous bleeding



Danger zone for small arterial branches and the adrenal vein
Danger zone for venous anomalies (retroaortic renal vein, large lumbar veins)

**Figure 88.3** Example of anticipating micro-events during left renal dissection that can result in preventable vascular injury.

Phase I (Damage Control)

1. How bad is the blood loss potential?
2. Is this likely arterial or venous in origin?
3. Can I realistically handle this laparoscopically with my skill set?

**Short term damage control maneuvers**

Notify anesthesia that there is a problem
Attempt to grasp the vessel or stump
Elevate pneumoperitoneum pressure
Introduce gauze and hold pressure

Phase II (Definitive Control)

1. Reassess response to damage control maneuvers
2. Decide on goal:
   a. Solve laparoscopically/robotically
   or
   b. Facilitate safe open conversion

**Permanent control**

GO GO

Get the necessary help in the room
Place additional ports, get more exposure
Clip, staple, bipolar, suture to solve problem
Try to avoid creating additional problems during fix

**Figure 88.4** Managing intraoperative bleeding during minimally invasive surgery.

and improve visualization. Communication is key in this situation. Stay calm and explain to the OR staff and anesthesiologist the situation and give specific instructions as to what is needed next. Anesthesia may need to catch up on fluid management or have blood transported into the room.

If temporary local control can be achieved with pressure and increased pneumoperitoneum, the next step is to set the stage for the definitive control phase. This may require placement of additional ports to facilitate laparoscopic suturing or improve exposure, getting additional or more experienced surgical assistants in the room, or accumulating specialty equipment needed for definitive control (e.g. Lapra-Ty® or Hem-o-lock® Clip appliers, proline sutures, etc.). In cases where local pressure is effective but exposure precludes definitive control, an assistant can be assigned to hold pressure while the primary surgeon performs additional dissection to improve access to the injury. If the surgeon feels that open conversion may ultimately be needed, this would be the time to prepare those instruments.

Smaller scale bleeding can usually be controlled by using either bipolar cautery or a radio frequency vessel sealant device (e.g. Ligasure™ or Enseal®). Larger vessels requiring repair can be closed by laparoscopic suturing. We prefer to use a 4-0 prolene suture on an SH needle with a Lapra-Ty and a knot on the end. A first pass through the both sides of the defect will approximate the edges and allows the surgeon to apply tension, facilitating exposure and the next throw. This approach is particularly applicable to vena caval injuries and does not require the placement of intracorporeal knots in a bloody field. Hilar bleeding during nephrectomy may often create a situation where the laparoscopic stapler has to be used earlier than anticipated for vascular control. Early mobilization of the kidney with lifting of the lower pole and dissection of the upper pole before marching toward the hilum is a good policy that improves exposure of the hilum and provides more options should a vascular injury subsequently occur. An important consideration prior to using a vascular stapler is the location of any metal or plastic vascular clips around the hilum which could cause a stapler misfire. We prefer to exclusively use a vessel sealer for perihilar dissection and only place clips after the vascular stapling has been completed. The adrenal and lumbar veins can be taken with a vessel sealer in most cases. A harmonic scalpel is a valid alternative but this device does not provide an auditory tone confirming vascular sealing and has an unguarded vibratory blade that can achieve high temperatures and injure surrounding structures if not carefully controlled. Always confirm the correct position of the stapler prior to firing. In a nondonor nephrectomy, it is usually advisable to move the stapler away from the caval or aortic insertion toward the kidney so as to leave a controllable stump behind in case of a misfire event (Figure 88.5). It is also critical to visualize the tip of the stapler prior to firing. This prevents loading too much tissue for effective staple occlusion and avoids pass-pointing and potential injury to structures behind the vessel.

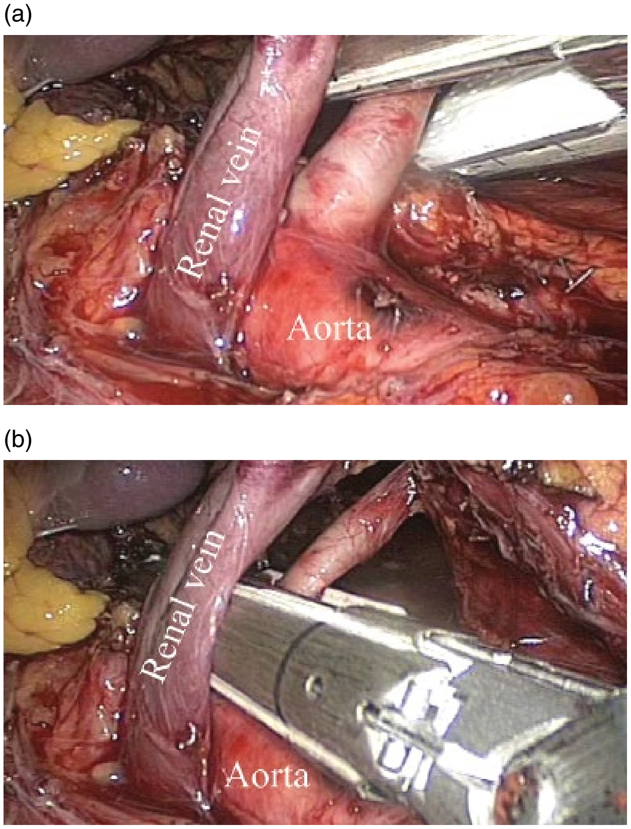


**Figure 88.5** Alternatives for endovascular stapler placement on the left renal artery. (a) Safer position: placing vascular stapler more distal on the renal artery to leave a stump. This makes it far easier to control should the stapler misfire. If a stapler misfire occurs, this position also allows proximal control of the renal artery prior to opening the stapler and may prevent major bleeding. Adequate exposure of the proximal artery minimizes the chance that an early branch will not be controlled by the stapler in this position. (b) More risky position: placing the vascular stapler flush to the surface of the aorta to transect the renal artery. In the event of a stapler misfire, this leaves a hole in the aorta which is far more difficult to control than a long renal artery stump. Note that the position flush with the abdominal aorta (b) may be necessary when it is essential to preserve vascular length (i.e. donor nephrectomy), but provides far fewer options for vascular control should the stapler misfire.

The specific circumstances of brisk bleeding during robotic surgery require some elaboration. Robotic-assisted laparoscopic procedures separate the console surgeon from the bedside assistant and necessarily create challenges during active bleeding. The robot provides some advantages, particularly during the definitive control phase, due to faster and more precise suturing. However, during the damage control phase, the robotic system may be disadvantageous. The bedside assistant is generally responsible for suctioning and providing exposure, rapidly changing instruments, and inserting gauze. Depending on the skill and experience level of the bedside assistant, this may not be ideal in a high-pressure situation. The console surgeon is also not scrubbed and is physically separated from the operative field, which can limit options to take over during critical steps of damage control.

In some cases, the scale of the vascular injury is simply too substantial to control with a minimally invasive approach. The goal in these situations should be a controlled, methodical open conversion that minimizes unnecessary blood loss and allows efficient control of the injury and completion of the surgery. The choice of incision should be dictated by what needs to be accomplished, not by the position of preexisting laparoscopic ports. For retroperitoneal cases, a subcostal or midline incision will likely be the most advantageous. In robotic cases, rapid removal of the robot from the field may be necessary and should be planned in advance. Maintaining pneumoperitoneum as long as possible may be beneficial in minimizing blood loss from large venous injuries. Prepacking the area with laparoscopic trocar-compatible laparotomy pads may also be advantageous prior to opening. Although rapid "crash" open conversions are occasionally required in cases of large arterial injuries, a controlled and organized open conversion will minimize blood loss when feasible.

## Postoperative bleeding

Postoperative bleeding, outside of the setting of uncontrolled coagulopathy, is usually due to an unrecognized vascular injury. During laparoscopic surgery, the pneumoperitoneum may tamponade venous bleeding that may manifest after the case is concluded and the abdomen is desufflated. Careful assessment of the entire operative field at low insufflation pressures (<10 mmHg) is prudent prior to desufflation and trocar removal. Trocars should also be removed under direct laparoscopic vision to exclude injuries to abdominal wall vessels (i.e. epigastric arteries) that may bleed postoperatively. Patients who are hemodynamically stable and present in a delayed fashion with declining hemoglobin can often be managed conservatively with blood transfusion. When re-explored, these patients frequently do not have a correctable source of blood loss [59]. In contrast, when patients present with early hemodynamic instability after laparoscopic surgery, surgical re-exploration is indicated and may identify an arterial injury that can be controlled.

A complication specific to nephron-sparing kidney surgery is the formation of renal arteriovenous fistulas or pseudoaneurysms [60–63]. A result of a vascular injuries within the kidney parenchyma during partial nephrectomy, pseudoaneurysms typically declare themselves 1–3 weeks after surgery with gross hematuria or other clinical signs of a bleeding [64]. These injuries are also seen after percutaneous nephrostolithotomy and renal biopsies. Selective angiographic embolization is usually the modality of choice to control bleeding and preserve renal function in these cases [64, 65].

## Injury to bowel and adjacent organs

Bowel injuries occur most frequently during abdominal access for laparoscopic surgery. A Cochrane meta-analysis reported equivalent complications rates for open versus closed (Veress) techniques with regards to their complication rate with an overall rate of visceral injury upon entry of 0.13% [66]. For closed access, common sense dictates avoiding the site of previous surgical scars. Once the Veress needle is placed, we prefer to aspirate with a syringe to ensure that neither blood nor bowel contents are encountered. Some surgeons prefer a saline drop test to be assured of proper placement within the peritoneal cavity. The goal is to avoid insufflation of a hollow or solid viscus or a vessel, which might lead to $CO_2$ embolus.

Today, there are a wide range of innovative technologies available to aid safe abdominal access in complex laparoscopic cases. These include the widespread use of optical trocars, which allow the surgeon to monitor passage of the trocar through the sequential layers of the abdominal wall. Other useful tools include 1.9 Fr laparoscopes that can be passed through a 2 mm trocar, working laparoscopes that facilitate lysis of adhesions, and single-site trocar options that allow open access and the use of multiple instruments through the same site (i.e. GelPOINT™; Applied Medical, Rancho Santa Margarita, CA, USA). The full spectrum of available options is beyond the scope of this chapter but the reader is directed toward several comprehensive reviews of this topic in the literature [66–68].

If a bowel injury with the Veress needle is suspected, a separate attempt to achieve access elsewhere in the abdomen may be indicated. Leaving the original needle in place aids in identifying the site of injury once laparoscopic access has been achieved elsewhere. Most injuries from a Veress needle do not require bowel resection although they may warrant reinforcement with an interrupted suture.

Sharp injuries to small and large bowel during operative dissection, when identified expeditiously, can generally be repaired primarily. Unfortunately, the most common laparoscopic bowel injuries are caused by electrocautery and should be managed more aggressively [69]. Fulgurated tissue needs to be excised before the enterotomy can be closed. For small bowel or colon injuries, interrupted suture with 3-0 polyglactin or silk on an SH needle. In cases of more significant injuries, a bowel resection and re-anastamosis may be required. Intraoperative general surgery consultation should be considered in these cases.

Many iatrogenic laparoscopic bowel injuries, particularly those caused by electrocautery or thermal injury, will not be recognized intraoperatively and will present in a delayed fashion [70]. In a recent large meta-analysis of >450 000 gynecologic laparoscopic procedures, 41% of the 604 bowel injuries presented in a delayed fashion [71]. In the urologic literature, as high as 69% of laparoscopic bowel injuries presented in a delayed fashion [69]. Some of these injuries are missed because they occur outside the surgeon's visual field due to instrument insulation defects or capacitive coupling [72, 73]. The risk of these injuries may be lessened by using shielded instruments with active electrode management [74]. The clinical presentation of delayed bowel injury after laparoscopic surgery can be subtle. These patients often present without the fever, leukocytosis, and diffuse abdominal exam findings (involuntary guarding, rebound tenderness) indicative of generalized peritonitis after open surgery. In contrast, patients who sustain bowel injuries during laparoscopic surgery often present with more subtle findings: localized trocar pain, abdominal distension, diarrhea, and leukopenia followed by cardiopulmonary collapse due to sepsis [69]. Surgeons should maintain a high index of suspicion for bowel injury in laparoscopic patients who do not progress appropriately after surgery and should have a low threshold to image these patients with CT scans.

Pancreatic injuries during urologic laparoscopy are rare (<0.5%) [75] but the organ is at risk due to the proximity of the pancreatic tail to the hilum of the left kidney and the left adrenal gland. Unrecognized pancreatic injuries can result in very significant morbidity. Management of pancreatic injuries identified during laparoscopic surgery often requires complex decision-making and we encourage intraoperative consultation with general surgery in these cases. In the absence of a clear injury but with some index of suspicion, draining the area with a close suction drain may be warranted.

Injuries to the spleen may occur during the release of the splenic flexure and the mobilization of the kidney from its splenic attachments during left nephrectomy or renal mobilization. Splenic injuries occur in 0.55–5.1% of these patients [76, 77]. Most splenic injuries result from indirect traction rather than direct perforation of the spleen with laparoscopic instruments. Small superficial capsular splenic tears can often be managed with a combination of bipolar cautery, argon beam coagulation and hemostatic products such as Surgicel® (Ethicon, Cincinnati, OH, USA) and fibrin glues [78]. More substantial and deeper lacerations to the spleen may require concurrent splenectomy [79]. Again, maintaining a low threshold to consult general surgery to assess a laparoscopic splenic injury and guide decision-making is appropriate.

## Injuries and complications associated with the urinary tract

Injuries to the urinary tract can occur during retroperitoneal and pelvic laparoscopic and robotic procedures. Identification and preservation of the ureters is an important step of procedures involving the kidney or pelvic vasculature. Likewise, injuries to the bladder can occur during pelvic surgery and should be identified and closed. Although ureteral injuries are uncommon during urologic, colorectal, and gynecologic procedures (<1% incidence), the relative risk of ureteral injury with laparoscopic surgery may be 4- to 6-fold higher than during open surgery [80, 81]. When ureteral injuries are identified intraoperatively, they can usually be repaired using minimally invasive techniques in experienced hands.

Variants of laparoscopic partial nephrectomy, including the robotic-assisted form, are now commonly applied procedures to treat most T1 and a subset of T2 renal masses. Over the past decade, the range of tumor characteristics considered appropriate for partial nephrectomy has expanded to include larger, more central and more complex tumors. These procedures often entail entry intro and resection of the kidney collecting system. However, the risk of postoperative urine leak remains <5% [82–85]. Management includes percutaneous drainage of the urinoma and occasionally collecting system decompression with either an internal ureteral stent or a nephrostomy tube if there is distal obstruction and poor drainage. In the absence of a large devascularized renal segment, almost all urine leaks with eventually close with conservative management.

## Injuries to the diaphram and pleura

The rate of inadvertent diaphragmatic and pleural injury during renal and adrenal laparoscopic surgery has been reported to be between 0.7 and 3.6% in large series of laparoscopic urologic cases [30, 86]. Despite the relative rarity of this complication, an unrecognized injury can result in tension capnothorax and cause significant intraoperative respiratory and hemodynamic distress. Diaphragmatic injuries occur most commonly when removing large upper pole renal or adrenal tumors or in the setting of substantial retroperitoneal inflammation obscuring normal tissue planes (i.e. xanthogranulomatous pyelonephritis). "Billowing" of the diaphragm during laparoscopic surgery should raise concerns about a diaphragmatic injury. Good communication between

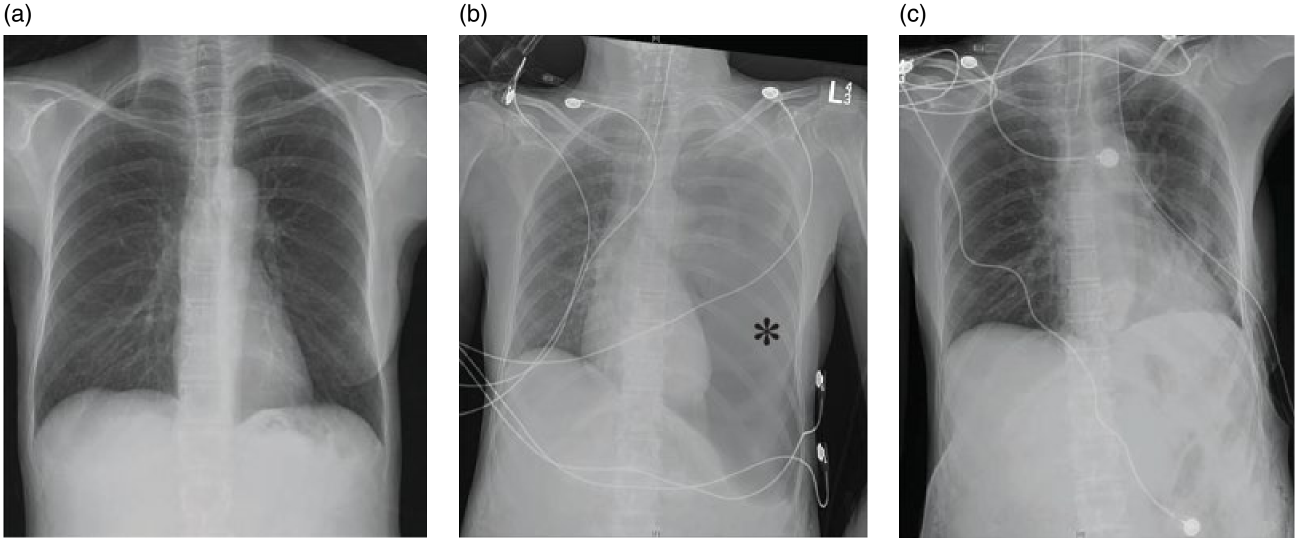

**Figure 88.6** (a) Preoperative. (b) Large left tension capnothorax (*) resulting in intraoperative respiratory and hemodynamic compromise during laparoscopic renal surgery. (c) Resolution with laparoscopic diaphragm repair and thoracostomy tube placement.

the surgical and anesthetic teams is important to recognize and address this problem uneventfully. Most small diaphragmatic/pleural injuries can be easily repaired laparoscopically with evacuation of $CO_2$ from the pleural space [86, 87]. Mesh and gelatin matrix have been used to successfully repair larger defects in the diaphragm [86, 88, 89]. Since $CO_2$ is much more rapidly absorbed than room air, a small to moderate capnothorax can often be managed conservatively without placement of a thoracostomy tube in a stable patient [90]. After diaphragmatic repair, we recommend an on-table chest radiograph prior to extubation to confirm lung reinflation. Patients with a large residual capnothorax or a tension capnothorax with hemodynamic/respiratory distress should be managed with immediate thoracostomy tube placement prior to extubation (Figure 88.6).

## Lymphatic leaks and chylous ascites

Injuries to small lymphatic vessels are common during laparoscopic retroperitoneal and pelvic dissection and generally heal without major sequelae. High-risk procedures for more significant leaks include those requiring extensive dissection along major vessels: retroperitoneal lymphadenectomy, donor nephrectomy and pelvic lymphadenectomy. Lymphatic leaks from damaged low pressure lymph channels can be challenging to identify under standard pneumoperitoneum pressures. Meticulous surgical technique to achieve lymphostasis using mechanical clips and vessel sealing devices can decrease the risk of postoperative lymphatic leaks and lymphocele formation. This is particularly important in the pelvis where lymphoceles can compromise venous return from the lower extremities and may increase the risk of deep venous thrombosis [43, 91, 92].

Chylous ascites (CA) is the accumulation of chyle (lymphatic fluid) within the peritoneal cavity (Figure 88.7) and can be a devastating complication of retroperitoneal laparoscopic surgery [93, 94]. CA can also result from congenital defects, inflammatory processes, or trauma. Following laparoscopic nephrectomy, the incidence of CA has been reported to be between 0.6 and 5.9% [95]. Abdominal aortic surgery is responsible for >80% of patients presenting with postoperative CA [96], likely due to injury to retroperitoneal lymphatics and the cisterna chyli [93]. The anatomic location of the cisterna chyli posterior to the left diaphragmatic crus puts it at risk during extensive vascular dissection above the left renal hilum, such as that required for laparoscopic donor nephrectomy [97, 98].

Clinically, CA may present early after surgery with milky fluid draining from surgical drains or directly from trocar sites. If assayed, the triglyceride content of this fluid will be high. Patients may be asymptomatic or manifest signs of ileus and abdominal distension. Untreated CA can result in severe malnutrition and protein loss. Once diagnosed, dietary management can be effective in controlling CA. Since dietary fat content determines the volume of lymphatic fluid derived from the bowel, fat restriction and a diet limited to medium-chain fatty acids can slow lymphatic leak. In many cases, total parenteral nutrition may be necessary to control the leak over a period of weeks. For persistent CA, management options include somatostatin analogs, paracentesis for symptom control, lymphoscintography, lymphangiography and occasionally surgical exploration [93–95].

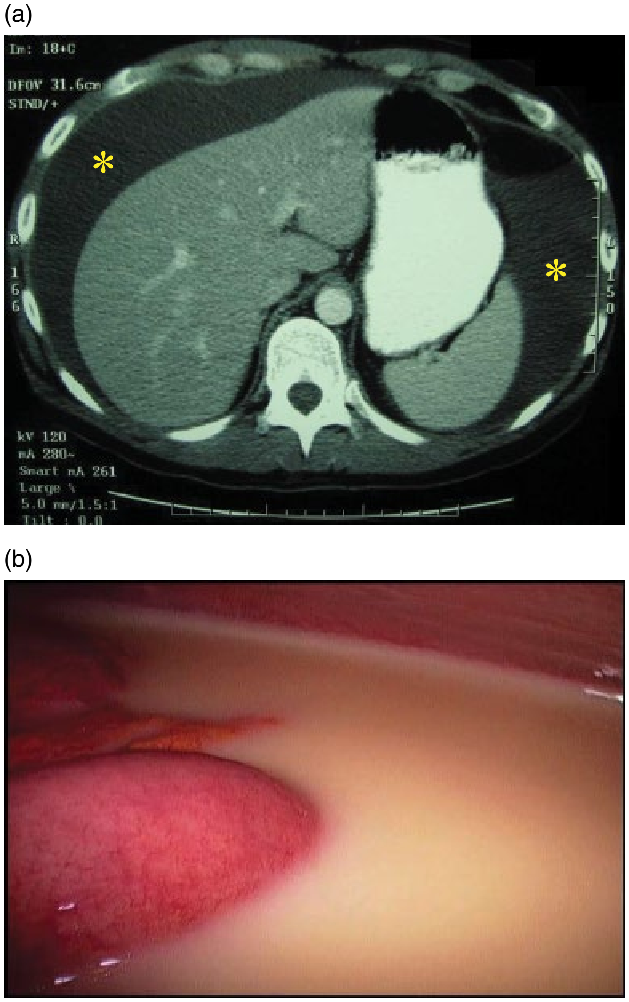

**Figure 88.7** Chylous ascites following retroperitoneal lymphadenectomy for testes cancer. (a) CT scan demonstrating a large volume of low-density fluid in the peritoneal cavity (*). ## Complications of robotic surgery

Robotic surgical systems have been used for urologic procedures since 2000 [99,100]. In addition to the complications seen in laparoscopic surgery, there are adverse events specific to the use of a robotic system. Software, electrical, or mechanical malfunctions may result in interruption or prolongation of a surgical procedure, conversion to laparoscopic or open surgery, reoperation, and, in rare instances, patient injury.

Device and instrument malfunctions include system errors, loss of video or imaging problems, falling of broken or burnt pieces into the patient's body, electrical arcing or sparking of instruments and broken tip covers, instruments not recognized by the system, instruments not working, and unintended or unstoppable instruments started without the surgeon's command [101, 102]. The electrical current leaking from monopolar scissors may result in thermal injury, and uncontrollable instruments may lead to direct tissue or organ injury.

Although device malfunction accounts for most of the reported adverse events, surgeon error during robotic surgery could also be a factor. There is a loss of tactile sensation during robotic surgery, and this lack of haptic feedback is usually adequately compensated for by the use of visual cues. However, in the hands of an inexperienced surgeon, robotic instruments may apply large forces on tissue, resulting in tissue injury.

Patient positioning is also critical during robotic procedures. For lengthy procedures, improper positioning of the patient may result in nerve injury and pressure ulcers. While a time-limited steep Trendelenburg position such as the one used during robotic prostatectomy is safe, a prolonged steep Trendelenburg has been shown to increase intraocular pressure in a time-dependent fashion [103, 104], and there have been reports of ischemic optic neuropathy after lengthy procedures in patients with preexisting ocular disease [105, 106]. It may also cause reduced venous outflow from the head, resulting in laryngeal edema and difficult extubation [107]. Shifts in patient position may sometimes go unnoticed as the surgeon is in a console away from the patient, and the robotic arms and extensive draping may partially block the view of the patient [108]. If this displacement is substantial, it may result in the robotic arms or the camera head delivering pressure damage to body parts such as the iliac crest, chest, or head.

Robotic instrument malfunctions are infrequent and most do not result in complications [102]. With adequate preventive measures, proper training and experience, robotic urologic surgery is at least non-inferior to laparoscopic or open surgery in terms of complication rates [109–111].

## Conclusion

In this chapter, we outline the common complications associated with laparoscopic and robotic urologic surgery. These complications are a function of (i) the specific physiologic stresses associated with pneumoperitoneum; (ii) the technical challenges inherent in the use of laparoscopic and robotic surgical instruments; and (iii) the organs and structures at risk in the retroperitoneum and pelvis where these procedures take place. Complications are unavoidable during surgery but anticipating and controlling the micro-events that cause them can help to minimize risk.

# Pelvic Lymphadenectomy

*Marc D. Manganiello*[1] *& Andrew A. Wagner*[2]

[1] *Tufts School of Medicine, Lahey Hospital and Medical Center, Boston, MA, USA*
[2] *Beth Israel Deaconess Medical Center, Boston, MA, USA*

## Introduction

Pelvic lymphadenectomy is the most accurate method of diagnosing lymph node involvement in patients with genitourinary malignancies. In practice, this is most commonly seen in patients with prostate and bladder cancer, but may also be performed in patients with penile or urethral cancers. Histologic confirmation of metastatic disease within the pelvic lymph nodes provides significant prognostic data and potentially therapeutic benefit. Additionally, this information may help guide the decision for future, adjuvant therapy [1, 2]. Minimally invasive pelvic lymphadenectomy (laparoscopic or robotic) offers a nodal yield similar to that from open surgery, but with improved convalescence [3]. Herein we describe the anatomy, procedure, and complications of minimally invasive pelvic lymph node dissection. Our procedure section specifically describes the robotic approach, but an identical dissection can be performed laparoscopically with similar benefits in visualization during the procedure and recovery afterwards.

### Accepted templates for pelvic lymph node dissection

There are varying definitions describing the extent of a pelvic lymph node dissection. Herein we describe the technique for each. The "limited template" (LT), also known as the standard template, lymph node dissection involves the nodes of the obturator fossa between the obturator nerve and external iliac vein. The lateral border of the dissection is the pelvic sidewall and medial border is the bladder. The tissue removed includes from the node of Cloquet to the bifurcation of the iliac vein proximally. The LT is commonly performed for low- and intermediate-risk prostate cancer. The "extended template" (ET) includes all the nodes in the LT, in addition to the nodes surrounding the external iliac artery back to the level of the common iliac artery at the level of the ureter crossing into the deep pelvis. The dissection also includes the tissue laterally from the external iliac artery to the genitofemoral nerve. Also included is tissue surrounding and deep to obturator nerve. The ET often includes the nodes in the presacral area. A "super extended template" (SET) includes the nodes of the LT and ET in addition to the nodes around the proximal common iliac artery and veins bilaterally up to the bifurcation of the aorta and the periaortic nodes up to the inferior mesenteric artery.

## Prostate cancer

Lymph node metastases in prostate cancer are reported to range from 4% to 6% in patients undergoing lymphadenectomy [4]. Nodal spread is associated with higher Gleason score, higher pT stage, older age, and higher incidence of positive surgical margin [5]. In addition, the number of positive lymph nodes found at surgery impacts overall survival. Patients with 1 or 2 positive nodes were found to have a clinical recurrence-free survival (no physical, radiographic, or symptomatic evidence of recurrence) of 70% and 73% at 10 years, whereas those with greater than 5 positive nodes were found to have a clinical recurrence-free survival of 49% at 10 years. This study did not compare prostate specific antigen (PSA), only recurrence between these groups. Overall survival between these two groups at 10 years was 74% versus 49% [6]. Touijer et al. reported a 78% overall 5-year progression-free probability for all prostate cancer risk groups, but noted a 49% 3-year progression-free probability in lymph node-positive patients. All of these patients experienced a clinical recurrence within 5 years [7].

## Lymph node imaging

Imaging has been consistently unreliable in diagnosing nodal metastases, particularly in patients with low-risk disease. The size criteria to identify possible lymph node involvement vary from 0.5 cm to 2 cm, although a lymph node with a short axis of 1 cm or greater is generally considered clinically abnormal. Computed tomography (CT) and conventional magnetic resonance imaging (MRI) have both demonstrated poor sensitivity for detecting nodal disease; one meta-analysis reported a pooled sensitivity of 0.42 and 0.39, respectively [8]. Evaluation of fluoromethylcholine positron emission tomography (PET)/CT for detection of lymph node metastases demonstrated a sensitivity and specificity of 73.2% and 87.6%, respectively. Neither the sensitivity nor the specificity is adequate enough to recommend PET/CT for routine use [9]. High-resolution MRI with magnetic nanoparticles has been shown to improve the sensitivity of detection of lymph node metastases, but has not yet been adopted as a recommended imaging option as availability of this technology is limited [10, 11]. Although current imaging modalities may not be ideal, significantly elevated preoperative PSA or high-risk biopsy pathology should prompt preoperative imaging. The American Urological Association (AUA) recommends preoperative imaging to evaluate for nodal disease in patients with clinically localized prostate cancer and a PSA greater than 20 ng/ml, locally advanced disease, or a Gleason score greater than or equal to 8 [12] (Table 89.1). The National Comprehensive Cancer Network (NCCN) recommends preoperative imaging with bone scan and pelvic CT or MRI if patients are cT1 and PSA greater than 20 ng/ml, cT2 and PSA greater than 10 ng/ml, locally advanced disease, symptomatic disease, or cT1–2 with a nomogram probability of lymph node involvement greater than 10% [13].

**Table 89.1** American Urological Association (AUA) and National Comprehensive Cancer Network (NCCN) criteria for preoperative imaging to evaluate for metastatic disease.

| American Urological Association | National Comprehensive Cancer Network |
|---|---|
| Clinically localized disease and PSA >20 ng/ml | T1 and PSA >20 ng/ml |
| Locally advanced disease | T2 and PSA >10 ng/ml |
| Gleason Score 8, 9, or 10 | Locally advanced or symptomatic disease |
| | Probability of lymph node positivity >10% |

## Who should undergo pelvic lymphadenectomy?

In an attempt to determine the need for pelvic lymphadenectomy, several nomograms exist to risk stratify patients prior to surgery. The Partin tables incorporate preoperative PSA, clinical stage, and biopsy Gleason score to predict the possibility of lymph node involvement, in addition to other adverse pathologic features (such as organ-confined disease, extraprostatic extension, and seminal vesical involvement). These tables were recently updated and confirmed the increased possibility of pT3 and N1 disease in patients with a PSA level >10 ng/ml. The Partin tables recommend that a pelvic lymphadenectomy be performed if the predicted probability of positive nodal disease is greater than or equal to 4%. This value gave the optimal ratio of appropriate to inappropriate lymphadenectomy [14].

Researchers from Memorial Sloan Kettering Cancer Center and several other institutions published a nomogram using similar variables of pretreatment PSA, clinical stage, and biopsy Gleason score. The negative predictive value of this nomogram was 0.99 when the predicted chance of lymph node involvement was less than 3%, thus obviating the need for lymphadenectomy in this subset of patients [15].

Briganti et al. recommended that patients with low-risk prostate cancer (Gleason 6, PSA <10 ng/ml, cT1c or cT2a) not routinely undergo pelvic lymphadenectomy as the chance of positive lymph nodes in these patients is less than 5% (Table 89.2). Intermediate-risk prostate cancer (Gleason 7, PSA between 10 and 20 ng/ml, or cT2b) carries a risk of positive lymph nodes between 3.7 and 20.1%, therefore, Briganti suggests lymphadenectomy should be performed if the nomogram risk is 5% or greater. All high-risk prostate cancer patients (Gleason 8–10, PSA >20 ng/ml, or cT2c) should undergo a pelvic lymph node dissection, as estimated risk is 15–40% for discovering positive lymph nodes [16].

**Table 89.2** European Association of Urology (EAU) and Briganti et al. recommendations for performing pelvic lymphadenectomy.

| EAU/Briganti – risk | Probability of positive lymph node | PLND? |
|---|---|---|
| Low (Gleason 6, PSA < 10, cT1c, cT2a) | Less than 5% | No |
| Intermediate (Gleason 7, 10 < PSA < 20, cT2b) | Greater than 5% | Yes |
| High (Gleason 8–10, PSA >20, cT2c) | 15–40% | All high-risk patients should undergo PLND |

PLND, pelvic lymph node dissection.

The European Association of Urology (EAU) guidelines for pelvic lymphadenectomy are based on a nomogram using a cohort of patients who underwent open prostatectomy and extended pelvic lymph node dissection template (ET). The EAU recommendation is to perform lymphadenectomy in patients who have a predicted positive nodal risk greater than 5% (based on findings by Briganti et al.). Using this cutoff for low-risk individuals, unnecessary pelvic lymph node dissection would be avoided in 65% of patients. This has been externally validated in a cohort of patients undergoing a robot-assisted radical prostatectomy, assuming that an adequate extended lymph node dissection is performed (i.e. at least 15 lymph nodes removed). Of note, in this study, there was no anatomic standardization of the pelvic lymph node dissection. Tissue within the obturator fossa and along the external iliac vein was removed in all patients. However, tissue along the internal and common iliac vessels was removed based on the individual surgeon's clinical judgment [16, 17].

Finally, the NCCN recommends performing a pelvic lymphadenectomy in patients with low- and intermediate-risk prostate cancer whose nomogram predicts a greater than 2% chance of positive lymph nodes (Table 89.3). All high-risk patients should undergo an extended template lymphadenectomy if surgery is performed [13].

**Table 89.3** National Comprehensive Cancer Network (NCCN) recommendations for performing pelvic lymphadenectomy.

| NCCN – risk | Probability of positive lymph node | PLND? |
|---|---|---|
| Low | If >2% | Yes |
| Intermediate | If >2% | Yes |
| High | | All patients |

## Rationale for extended pelvic lymphadenectomy template in prostate cancer

Lymphatic drainage from the prostate follows a fairly predictable pattern, with low chance of skip lesions. Drainage occurs first to the pelvic nodes in the external iliac, obturator, internal iliac, and presacral lymph node packets. Lymph drainage may then ascend to the common iliac and retroperitoneal lymph nodes; however, this is generally seen only in patients with high-risk prostate cancer [18]. Pelvic lymph node mapping in prostate cancer has demonstrated that the most common location for a positive lymph node was the internal iliac region (35%), followed by the external iliac region (26%), the obturator fossa (25%), presacral region (9%), common iliac region (3%), and the aortic bifurcation (1%) [19]. There has been some controversy over the extent of lymph node dissection given the technical difficulties and the potential for further and possibly unnecessary complications. Early reports of extended lymphadenectomy published complication rates of 12–24% and included lymphocele, lymphedema, and thromboembolic events. This led to development of the limited dissection template or the obturator fossa packet [20]. Clark et al. prospectively randomized 123 patients undergoing radical retropubic prostatectomy to an extended lymph node dissection on one side and a limited lymph node dissection on the opposite side. The majority of these patients were T1c (72%) and Gleason 6 (68%). Positive lymph node metastases were similarly found between the extended (3.3%) and the limited (2.4%) groups ($P = 0.15$). In patients with complications attributed to the lymph node dissection (i.e. lymphocele, lower extremity edema, deep venous thrombosis, pelvic abscess, ureteral injury) the complication occurred 75% of the time on the side of the extended node dissection. Although this finding was not clinically significant ($P = 0.08$), the authors concluded that an extended lymph node dissection does not yield a higher rate of positive lymph nodes and that there may be a trend toward higher complications with an extended pelvic lymph node dissection [21]. On the other hand, Eden et al. describe a series of 374 men who had a pelvic lymph node dissection during laparoscopic radical prostatectomy. Of these, 253 men had a standard lymph node dissection, while 121 men underwent an extended template. The operative time for an extended template was significantly longer by a median of 26.5 minutes (180 vs. 206.5 minutes, $P < 0.001$). Although there were more complications (i.e. bowel injury, neurovascular injury, lymphocele) with an extended template as compared to a standard template (8.3% vs. 3.6%), this was not found to be statistically significant ($P = 0.10$). Importantly, in patients undergoing an extended pelvic lymph node template versus a standard template, there was a significantly higher total lymph node yield (17.5 vs. 6.1, $P = 0.002$) as well as a higher rate of detection of lymph nodes harboring metastatic disease (9.6% vs. 0.8%, $P = 0.01$) [22].

The important distinction comes in patients with intermediate- and high-risk disease. A significant amount of nodal disease may occur outside of the ST, thus the importance of extending the template to include the common iliac, internal iliac, and presacral regions. Several studies demonstrate that almost 60% of patients harbored positive lymph nodes along the internal iliac vessels; in fact, this was the only site of lymphatic spread in 12–25% of patients undergoing prostatectomy [19, 23]. By extending the template of dissection, more lymph nodes are removed and the accuracy of staging improves. Briganti et al. demonstrated that the number of nodes removed is directly proportional to the probability and ability of detecting lymph node involvement. For each lymph node removed, the probability of accurately predicting lymph node involvement in a patient with prostate cancer increases by 6%. If fewer than 10 nodes are removed, there is less than 10% probability of finding lymph node involvement if it actually exists. In contrast, as the number of nodes removed increases from 10 to 30, the probability of detecting positive lymph nodes increases substantially. This plateaus when 28 lymph nodes are removed, resulting in a 90% ability to accurately predict whether or not lymph node involvement is present [24]. Maccio et al. have recommended submitting the entire pelvic lymph node specimen, including fatty tissue, for pathological evaluation, not just examining visually enlarged or palpable nodes. Incidence of nodal metastasis was significantly higher when all fatty tissue removed at the time of dissection was histologically evaluated. This minimized pathologic diagnostic bias and helped to determine the presence of micrometastatic disease [5].

In addition to improving the accuracy of disease staging, an extended lymph node dissection may improve survival. Abdollah et al. found that in pN1 patients with prostate cancer, cancer-free survival rates increased as the number of lymph nodes removed increased. For example, at 10 years after surgery, the cancer-free survival for a patient with 8 lymph nodes removed was 74.7%; this improved to 96.0% when 36 lymph nodes were removed. In general, survival rates were significantly higher in pN1 patients with more than 14 lymph nodes removed compared to patients with less than 14 lymph nodes removed [25]. Extended lymph node dissection may also improve the survival in pN0 patients as well. Joslyn et al. reported that when greater than 10 lymph nodes were removed, node-negative patients were found to have a 15% decreased risk of prostate cancer death [26].

## Bladder cancer

The standard of care for muscle invasive urothelial cell carcinoma of the bladder is radical cystectomy with bilateral pelvic lymph node dissection. Positive lymph node status and pathologic stage are associated with a worse overall prognosis and survival. Approximately 25% of patients undergoing radical cystectomy are found to have lymph node metastases [27]. These patients have a reported 5-year recurrence-free survival of 33% and overall survival of 26% [28]. An aggressive surgical approach has consistently demonstrated both a diagnostic and therapeutic advantage [29, 30].

### Preoperative imaging

Initial metastatic workup for patients with muscle invasive urothelial carcinoma includes cross-sectional, contrast-enhanced imaging with either CT or MRI. Sensitivity and specificity of these imaging studies are suboptimal, similar to lymph node detection in prostate cancer [31, 32]. Roughly 25% of individuals whose preoperative imaging studies were negative for lymph node involvement were found to have lymph node involvement on final pathology [27]. PET/CT has been evaluated as a potential modality; however, the false-negative rate was 33% and it has not been found to be helpful in evaluating patients with primary bladder cancer. Thus it is currently not a recommended imaging option [33].

### Template for pelvic lymphadenectomy during radical cystectomy

The template for pelvic lymphadenectomy in urothelial cell carcinoma is controversial insofar as it has been shown repeatedly that increasing the node yield results in improved survival, yet it is common for surgeons both in academia and community practices to omit part or all of the dissection. At a minimum, the dissection should include an ET lymph node dissection: removing tissue overlying the external iliac, internal iliac, presacral, obturator fossa, and distal common iliac up to the crossing of the ureter [27] (Figure 89.1). A SET has been advocated

Reproduced with permission of Elsevier.

by some groups for improved staging and therapeutic benefit and includes removal of tissue along proximal common iliac artery and vein, the distal vena cava and aorta up to the level of the inferior mesenteric artery [34]. Although an ET or SET lymph node dissection has been shown to increase operative times by at least 60 minutes, there does not appear to be an increase in perioperative morbidity, complications, or blood transfusions [35].

### Therapeutic benefit of pelvic lymphadenectomy and rationale for extended template dissection

Extended pelvic lymph node templates (ET) result in improved staging accuracy as well as improved overall survival when compared to LT dissection [27, 33, 36]. It is unclear if the SET is superior to the ET in terms of recurrence-free survival [34]. Regardless of the template, it appears there is a tangible benefit to removing a greater number of lymph nodes during a radical cystectomy for high-risk bladder cancer. Herr et al. reported on a group of 322 patients with muscle invasive transitional cell carcinoma who underwent radical cystectomy and bilateral pelvic lymphadenectomy, 258 (80%) of whom had node-negative disease and 64 (20%) with node-positive disease. In both node-negative and node-positive patients, there was a statistically significant survival advantage when a greater number of nodes were removed. For example, in node-negative patients, when 9 or more lymph nodes were removed a statistically significant survival advantage was demonstrated as compared to removal of 4–7 nodes or 0–3 nodes. Furthermore, in node-positive patients, a significant survival advantage was found when more than 14 nodes were removed, as compared to removal of 9–14 or 1–8 nodes. In addition to complete surgical removal, the authors also note the importance of a thorough pathological assessment when examining the specimen [37]. Leissner et al. demonstrated that when <16 lymph nodes compared with >16 lymph nodes were removed during surgery, 5-year recurrence-free survival rates improved from 63% to 85% in organ-confined tumors and 40–55% in locally advanced tumors [29]. Both node-negative and node-positive patients appear to benefit from an ET lymph node dissection. Patients with organ-confined, lymph node-negative disease were found to have a 90% 5-year recurrence-free survival after extended pelvic lymph node dissection as compared to a 71% 5-year recurrence-free survival with a more limited ST pelvic lymph node dissection [38]. In addition, 5-year recurrence-free survival in patients with lymph node-positive disease was improved in patients undergoing an extended lymph node dissection versus a limited dissection (24% and 7%, respectively) [33].

In an effort to understand further the importance of lymph node positivity in bladder cancer, the concept of lymph node density has been described. Lymph node density is defined as the number of lymph nodes containing metastatic disease divided by the total number of lymph nodes removed. This concept helps to risk stratify patients with node-positive disease. Variations in surgical templates and technique of gross pathology analysis must be considered when using lymph node density. It is also difficult to compare these data across institutions as there are large variations in technique of gross analysis of the node packets. For example, some centers send node packets separated by anatomic location. Other centers send the pelvic node packet en bloc. These differences may affect total node count. However, in general, multiple groups have demonstrated that higher lymph node density translates into poorer overall survival [39].

## Surgical anatomy

In general, the pelvic lymph node dissection is performed during the same operative time as primary tumor removal (i.e. during radical prostatectomy or radical cystectomy) (Figure 89.2). When performed robotically or laparoscopically, we recommend performing any extended (ET or SET) node dissection prior to primary tumor removal. We prefer this approach because the node dissection arguably requires the highest level of concentration of the entire procedure. Performing the node dissection first allows the surgeon maximum concentration for the meticulous dissection in and around the large vessels of the pelvis. Moreover, the surgical anatomy prior to the cystectomy can become slightly altered after ligation of the vascular pedicles (i.e. excessive staple lines or clips near the internal iliac vessels can create challenges dissecting in this area). A transperitoneal approach is recommended for ET or SET dissections, as the visualization is improved of the proximal aspects of the dissection near the common iliacs when compared to an extraperitoneal approach. Prior to the procedure, the pelvic anatomy is inspected. In the midline, along the anterior abdominal wall, is the urachus or median umbilical ligament. This spans from the dome of the bladder cephalad to the umbilicus. On either side, lateral to the urachus are the medial umbilical ligaments (obliterated umbilical arteries), originating from the internal iliac arteries as the first anterior branch. The ureter will be identified medial to the medial umbilical ligaments, an important anatomic landmark for ureteral mobilization during cystectomy. Lateral to the medial umbilical ligaments are the lateral umbilical folds, under which are the inferior epigastric arteries. It is important to be aware of these folds in order to avoid injury, especially

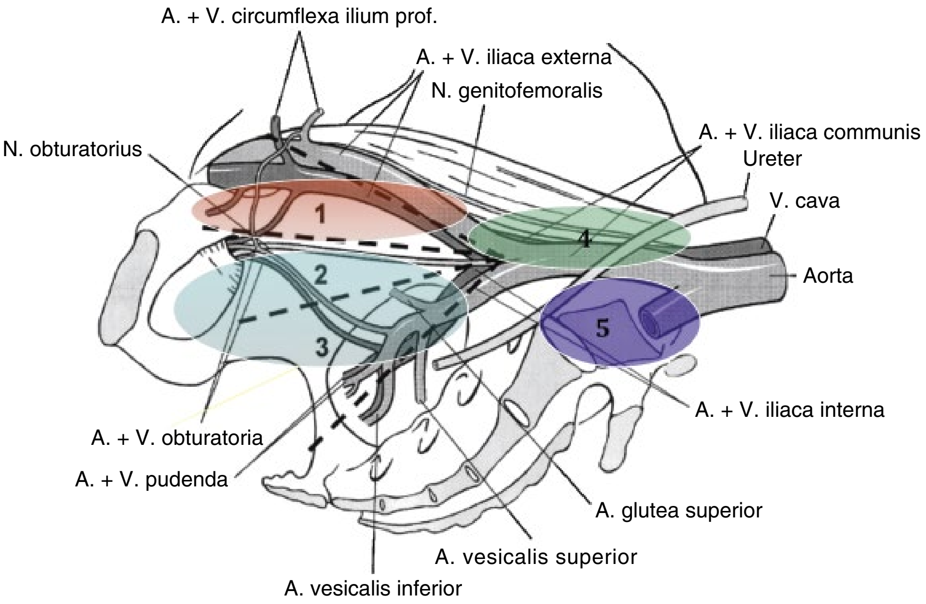

**Figure 89.2** Anatomic limits of pelvic lymph node dissection (PLND). Area 1 (red): limited PLND. Areas 1–3 (blue): standard PLND. Areas 1–4 (green): extended PLND. Reproduced with permission of Elsevier.

during trocar placement and bladder mobilization from the anterior abdominal wall.

The abdominal aorta bifurcates near the level of L4 into the right and left common iliac arteries. The common iliac arteries are in danger of injury during initial, periumbilical trocar placement. The ureter crosses over the common iliac artery and into the pelvis just proximal to the bifurcation of the common iliac into the external and internal iliac arteries. The external iliac artery is found lateral and anterior to the external iliac vein, exiting the pelvis through the femoral canal. The pelvic organs are supplied by branches of the internal iliac artery, including the superior and inferior vesical arteries, obturator artery, vaginal and uterine arteries (in females), middle rectal artery, internal pudendal artery, and the inferior gluteal artery. Importantly, the left common iliac vein runs underneath the right common iliac artery. This structure may easily be injured during an extended lymph node dissection as tissue is cleared around the common iliac vessels and bifurcation of the aorta. In particular, during a presacral node dissection the left common iliac vein is often found under a layer of nodal tissue just proximal to the sacral promontory. This needs to be identified during the dissection to avoid inadvertent injury.

The ureter runs anteromedial to the internal iliac artery and its branches (i.e. the medial umbilical artery and the superior and inferior vesical arteries). In females, the ureter runs underneath the uterine artery, contained in the cardinal ligament. This is a common area of ureteral injury during gynecologic procedures. The ureter then courses posterior to the vas deferens, inserting into the trigone of the bladder. The vas deferens, or the round ligament in the female, exits the internal inguinal ring, running medially, over the external iliac vessels and anterior to the ureter.

The genitofemoral nerve is the lateral border of the pelvic lymph node dissection. This nerve runs along the anterior surface of the psoas muscle, medial to the gonadal vessels and lateral to the external iliac vessels. The genitofemoral nerve splits with the genital branch running through the internal ring with the spermatic cord and the femoral branch running to supply the anterior thigh. The obturator nerve has components of the second, third, and fourth lumbar nerves and supplies the motor function of the adductor compartment of the thigh as well as the sensory function of the medial thigh. The nerve exits the medial border of the psoas muscle behind the bifurcation of the internal and external iliac veins, and runs laterally along the pelvic sidewall. The internal iliac artery is found medial and below the nerve, while the external iliac vessels are found lateral and above the nerve. Posterolateral to the common iliac vessels is the fossa of Marseilles. This area includes the tissue lateral to the common iliac vein over the obturator nerve as it exits the psoas muscle. In this region is presciatic lymph tissue, commonly incorporated in the extended pelvic lymph node dissection. The obturator nerve exits the pelvis distally through the obturator foramen.

## Robotic port placement and robot positioning

The patient is placed in the supine position with legs split and pressure points carefully padded, including the heels, calves, elbows, wrists. Pneumo-boots and subcutaneous heparin are used for thrombosis prophylaxis. The patient's right arm is placed in an arm protective device (ArmGuard$^{TM}$, D.A. Surgical, Chagrin Falls, OH, USA) securing it at his or her side. The patient's left arm is secured at his or her side. A Trendelenburg patient restraint device (e.g. TrenGuard 405$^{TM}$, D.A. Surgical) is placed above the neck and shoulder supports are secured by Velcro to the operative bed. The patient is then placed in full Trendelenburg position to ensure that they are secured. The patient is returned to flat supine position and prepared and draped in sterile fashion. A Foley catheter is placed on the sterile field. Abdominal access is achieved via either a Veress or Hassan technique, depending on surgeon preference. Once proper placement of the needle is confirmed, the abdomen is insufflated to 15 mmHg through the umbilicus. The abdomen is not marked for potential trocar sites until fully insufflated, as landmark positioning will change (Figure 89.3).

For those surgeons using the da Vinci Si system (Intuitive Surgical Inc., Sunnyvale, CA, USA), a 12 mm camera port marking is placed in the midline, superior to the umbilicus. The da Vinci Xi system uses an 8 mm camera placed at the same location. The first and second 8 mm robotic ports are placed roughly 8 cm lateral to the umbilicus and 18–20 cm cephalad from the base of the penis (Figures 89.4 and 89.5). We routinely move these ports in a cephalad direction, especially if an ET node dissection or an intracorporeal urinary diversion is planned. Thus, in these cases, the ports are often at the level of the umbilicus or slightly above. The right anterior superior iliac spine (ASIS) is palpated and the 12 mm assistant port is placed in a triangulated location between the ASIS and the right 8 mm robotic port. The left ASIS is palpated and the robotic third working arm port is placed at a location which is triangulated between the ASIS and the robotic second port. Finally, a 5 mm port is placed in the right upper quadrant in a

triangulated location between the camera port and the robotic first arm, although this may be moved slightly in a lateral direction, so that it is cephalad to the robotic first arm.

All port sites are infiltrated with 0.5% bupivacaine prior to incision. The abdomen is entered visually using a 0° laparoscope through a 12 mm optical bladed visualization trocar (Visiport$^{TM}$, Medtronic, Minneapolis, MN, USA) above the umbilicus. The abdomen is inspected for injury, evidence of metastatic disease, and feasibility of proposed port site placement (ensure no significant potential for bowel injury due to adhesive disease). Each port site is incised and the trocar placed under direct vision. The patient is then placed in a moderate Trendelenburg position (about 15–20°), with just enough tilt to allow the small bowel to fall out of the pelvis with some gentle retraction by the assistant. If present, adhesions are taken down to allow for optimal exposure and bowel mobilization. We routinely avoid steep Trendelenburg position to avoid associated airway difficulties as well as elevated intracranial and intraocular pressures.

The robotic patient cart is then prepared for docking. It is brought between the split legs of the patient, such that the robot is directly facing the perineum. It is important to place the robotic arms at an adequate height so as not to impinge on the lower extremities of the patient either while docking or during the procedure itself. In particular, the robotic third working arm can impact the toes of the patient in Trendelenburg position. A 0° or a 30° telescoping camera lens may be used. It is our practice to use monopolar scissors in the robotic right hand, fenestrated bipolar forceps and Maryland bipolar forceps in the robotic left hand, and Prograsp forceps in the robotic third arm. The assistant has access to a small bowel atraumatic grasper, suction, laparoscopic clips, laparoscopic needle driver and scissors, and a spoon.

## Procedure

Robotic pelvic lymph node dissection is generally performed during the same procedure as the prostatectomy or cystectomy. If an extended pelvic lymph node dissection (ET) is planned, it is most easily performed prior to beginning the prostatectomy or cystectomy so as to maintain the normal anatomic planes without disruption from staple lines or clips. If a standard template is planned (lower risk prostate cancer) then this can easily be performed either before or after the prostatectomy.

During robotic prostatectomy, the first step is the identification of landmarks. These include the medial umbilical ligament, the ureter, the vas deferens, and the external iliac artery (Figure 89.6).

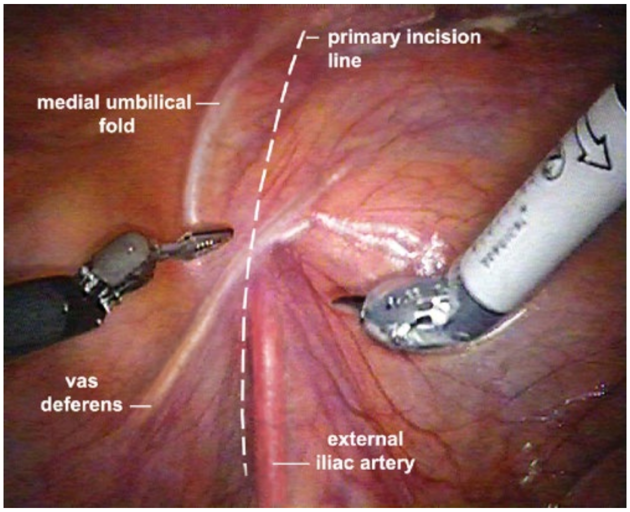

**Figure 89.6** Primary incision line and identification of landmarks (right side). *Source:* Feicke A, Baumgartner M, Talimi S et al. Robotic-assisted laparoscopic extended pelvic lymph node dissection for prostate cancer: surgical technique and experience with the first 99 cases. *Eur Urol* 2009 Apr;55(4):876–884. Reproduced with permission of Elsevier.

Once the pelvis has been cleared of significant adhesive disease, the ureter is most easily identified at the pelvic brim as it crosses over the common iliac artery. We routinely perform right-sided lymphadenectomy first by identifying and, if necessary, dissecting the right ureter away from the pelvic sidewall. The sigmoid colon is often adhered to the left pelvic sidewall, allowing this to be easily retracted out of the pelvis and away from the right sidewall. This facilitates visualization of the right iliac vessels and right ureter. To begin, a peritoneal incision is created over the right ureter and extended medially to the sigmoid mesentery. The ureter is then identified and peritoneum incised anterior to the ureter as it courses down into the deep pelvis. The fatty tissue around the ureter is dissected with the ureter and care is taken not to skeletonize the ureter and strip it of its blood supply. The ureter is dissected down to the bladder hiatus, clipped and divided distally. It is dissected proximally to the level of the mid ureter as it overlies the psoas muscle. During the dissection the bedside assistant should have a grasper or probe which can be placed under the ureter to create mild countertraction, aiding in the dissection. Once the ureter is clipped distally and dissected proximally, the extended pelvic lymph node dissection for radical cystectomy can begin. If an ET dissection is being performed prior to a prostatectomy, the peritoneal window is created over the ureter as described above, however the ureter is identified and gently retracted cephalad to begin the node dissection over the bifurcation of the iliac artery.

To begin the lymph node dissection, the adventitia overlying the right common iliac artery is incised to reveal the direct surface of the vessel. We use a fenestrated bipolar grasper in the left hand and a curved monopolar scissors in the surgeon's right hand. The bipolar grasper is used to help with hemostasis of the tissue over the artery and the tissue is "split and rolled" laterally and medially. This requires some countertraction on the artery with the left hand and gentle sweeping motions with the scissors in the right hand. Most of the fibrinous adhesions of the nodal tissue to the artery surface are incised sharply without cautery. This dissection moves distally to the external iliac artery. As the peritoneum and fibrofatty tissue are dissected distally along the external iliac artery, the vas deferens will be encountered, which is ligated using bipolar cautery or clips. The peritoneal incision is extended distally, lateral to the medial umbilical ligament to reveal the node of Cloquet which is the distal extent of the dissection. Locking clips or laparoscopic metal clips are used to secure small lymphatics here to prevent excessive lymph leak.

As this tissue is removed, retraction of the node packet is facilitated with a combination of the surgeon's thirrd working arm and the bedside assistant's laparoscopic suction irrigator or atraumatic graspers to provide countertraction to aid in the dissection. The genitofemoral nerve may be visualized lateral to the external iliac artery and identifies the lateral extent of lymphatic tissue removal. The distal aspect of the dissection is at Cooper's ligament and the pubic bone.

Tissue is rolled laterally off the external iliac artery and dissection proceeds along the pelvic sidewall behind the vessels. Much of the pelvic node dissection is performed from behind the vessels, allowing better visualization of the lateral borders of the dissection. The external iliac vein is immediately identified behind the artery and again the tissue on the anterior surface of the vein (but visualized behind the artery) is incised and split and rolled medially and laterally. Again, the tissue is sharply incised if directly on the surface of the vessel. There may be small perforating venous branches which can be ligated with clips or bipolar cautery. Using blunt dissection through this fibrofatty tissue will help to identify the obturator nerve, which is carefully separated from the packet without the use of electrocautery. We take care to attempt to remove the nodal tissue deep to the nerve as well, using clips to ligate the tissue. Obturator vessels are commonly seen running alongside this nerve (Figure 89.7).

As the dissection moves proximally, the internal iliac artery is identified. The tissue over the internal artery is often more adherent than that over the external artery. Again, the tissue directly over the internal artery is ligated with bipolar current and the tissue lateral is rolled off to reveal the obturator nerve. The dissection continues

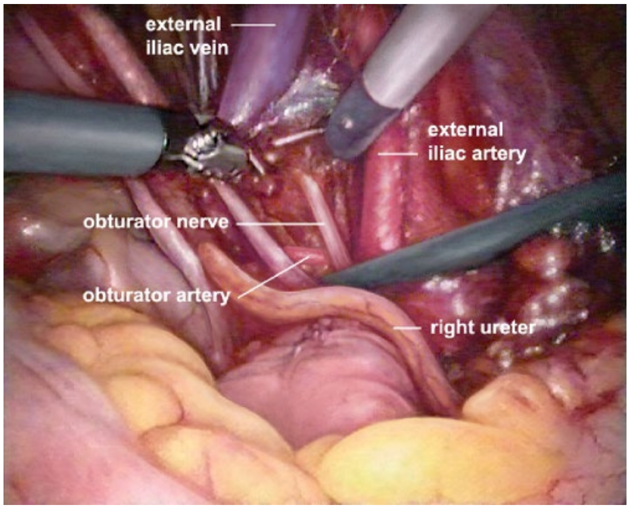

**Figure 89.7** Identification of the obturator nerve at its proximal course after separating the external iliac artery and vein (right side). *Source:* Feicke A, Baumgartner M, Talimi S et al. Reproduced with permission of Elsevier.

distally until the insertion of the medial umbilical ligament is identified into the internal iliac artery (Figure 89.8).

After completing the right pelvic node packet we begin the presacral lymph node dissection. The robotic third arm is used to aggressively retract the sigmoid and its mesentery to the left. The dissection is begun by first identifying the medial aspect of the right internal iliac artery. The tissue here is rolled medially, peeling it down to the presacral area and identifying the left common iliac vein as it crosses under the right common iliac artery. Blunt spreading here is crucial to avoid lacerating the vein. Once the vein is identified, the tissue just distal to the vein is peeled away from the sacral promontory. Again, generous use of metal or locking clips is advised as the tissue is quite vascular. A difficult aspect of this dissection is the demarcation of sigmoid mesentery with actual presacral node packet (anterior border of the presacrals). There is usually a subtle plane identifying the two layers, but it is challenging and the ability to identify the correct tissue improves with experience. The tissue is dissected to the left until the left internal iliac artery is identified, where the tissue is then ligated and removed.

A completed presacral dissection allows for relatively easy identification of the left common iliac and ureter under the sigmoid mesentery from the right side. A large aperture is created under the sigmoid mesentery, allowing for easy transfer of the left ureter to the right side.

The left side pelvic node dissection is then dissected in a similar manner. Often the sigmoid must be mobilized off the left sidewall to allow visualization of the ureter, which is identified and dissected distally, again incorporating the periureteral fatty tissue into the dissection. The sigmoid must then be retracted aggressively to the right to improve exposure to the left pelvic sidewall. In the case of the radical cystectomy, the ureter has already been identified, clipped, divided, and placed proximally out of harm's way. In a similar procedure to the patient's right pelvic lymph node dissection, the fibrofatty tissue overlying the left common and external iliac arteries is incised. This tissue is split and rolled off the artery and dissection proceeds distally. The vas deferens is encountered and ligated. After incising the peritoneum lateral to the medial umbilical ligament, the pubic bone and Cooper's ligament are encountered and the lymphatic vessels distal to Cloquet's node are clipped and divided. The tissue lateral to the artery is first dissected back proximally to the common iliac, clipped and ligated. The remaining pelvic nodal tissue is then approached from behind the vessels and separated from first the external vein, and then the sidewall itself. Again much of the dissection is done from behind the vessels, allowing for improved visualization of the obturator nerve and external iliac vein. The obturator fossa is encountered and dissection is carried to the pelvic sidewall. The obturator nerve and accompanying vessels are identified. Fibrofatty tissue in the internal iliac packet is dissected and clipped. Both pelvic lymph node packets are placed in a specimen bag for removal at the conclusion of the procedure.

## Complications

Intraoperative complications directly related to pelvic lymph node dissection include damage to pelvic vasculature and nerve damage to the obturator nerve. Specifically, in the pelvis, injury may occur to the common iliac, external iliac, and internal iliac vessels, as well as their branches. Depending on the nature of these injuries, there should be consideration for a vascular surgery consult. Many vascular injuries can be repaired primarily using robotic intracorporeal suturing techniques. We use a 5-0 prolene cut to 12.7 cm, which is our "rescue suture" (i.e. always opened on the backtable in the event that vascular repair is necessary). If immediate vascular control and visualization of the injury is not obtained, then conversion to an open repair is mandatory. The obturator nerve may be injured via thermal energy or crush, especially if this structure has not been well defined. In particular, the obturator can be inadvertently clipped proximally near the bifurcation of the iliac vessels. It needs to be visualized at all times when clipping in the area.

Postoperative complications from a pelvic node dissection can include ileus, small bowel obstruction, lower extremity deep venous thrombosis (DVT), wound infection, and lymphocele. Lymphoceles are usually managed conservatively. However, if large, they may cause a DVT from compression of pelvic veins, may compromise the urethrovesical anastomosis, or may become secondarily infected. Treatment options include percutaneous drainage or creation of a peritoneal window. In an extended lymph node dissection during a radical prostatectomy, the ureter may be injured as it crosses the common iliac. Thus it should be identified prior to beginning the dissection and kept out of harm's way (see Video 89.1).

# Endoscopic Subcutaneous Modified Inguinal Lymph Node Dissection for Squamous Cell Carcinoma of the Penis

*Jay T. Bishoff*[1] *& Kefu Du*[2]

[1] *Intermountain Urological Institute, Intermountain Health Care, Salt Lake City, UT, USA*
[2] *Division of Urologic Surgery, Washington University School of Medicine, St. Louis, MO, USA*

## Introduction

The presence and extent of metastatic disease to the lymph nodes is the most important prognostic indicator of survival in patients with squamous cell carcinoma of the penis and has significant clinical application for cutaneous melanoma and vulvar cancer. Lymphadenectomy is often required in these disease processes for cancer staging and can also be curative when cancer is isolated to the penis and regional nodes. Serious life-altering complications have been associated with inguinal lymph node dissection. Due to the substantial morbidity caused by inguinal lymphadenectomy, controversy surrounds the utility of bilateral and prophylactic dissection.

In 2002 Ian M. Thompson MD conceived the idea of applying laparoscopic techniques in an endoscopic approach to the inguinal lymph nodes, with the hope of decreasing the morbidity associated with open surgery by preserving the continuity of the lymphatic and vascular supply to the overlying skin. Working together, we combined various techniques from subcutaneous endoscopic brow lift and saphenous vein harvest to formulate an approach using laparoscopic instruments for inguinal node dissection in staging penile cancer. The result of our work was the endoscopic subcutaneous modified inguinal lymphadenectomy (ESMIL) procedure, which mimics the same oncological approach traditionally performed through an open incision.

We first explored the feasibility of this new procedure in several fresh cadaver studies and then finally in 2003 a patient with T3 N1 M0 squamous cell carcinoma of the penis underwent the first ESMIL procedure [1]. Since our initial report, others have used the technique with great success and have applied the same technique to penile and other cancers requiring inguinal node dissection [2–7]. Each series demonstrated reduced skin necrosis, reduced lymph edema, and fewer infections when compared to open surgery.

The key points of ESMIL are summarized in Box 90.1.

## Indications/contraindications

ESMIL is indicated when traditional inguinal lymphadenectomy would be required for staging squamous cell carcinoma of the penis. Patients with nonpalpable nodes or small (<1 cm) mobile nodes at high risk for inguinal node involvement are considered good candidates for endoscopic node dissection. Patients with pTa and pT1 grade 1 penile tumors will have positive nodes approximately 10% of the time, when inguinal nodes are not enlarged. Fifty percent of patients with pT2 tumors and G3 tumors will demonstrate positive inguinal lymph nodes.

Both stage and grade are predictive of nodal involvement. Verrucuous carcinoma and carcinoma in situ are both associated with a low risk for nodal metastasis. However, 70% of stage T2 cancers have positive nodes. Grade I tumors have a 30% chance of spread to lymph nodes, while approximately 85% of patient with grade III tumors have inguinal node involvement [8]. Because cross-drainage from the affected side to the contralateral side is a well-known occurrence, bilateral dissection is indicated in patients at high risk for metastatic disease (stage T2 or greater or grade II–III tumors).

Patients with large, fixed inguinal lymph nodes have a relative contraindication to ESMIL. In these patients it can be very difficult to dissect the superior aspect of fixed, matted lymph nodes with an endoscopic technique and as a result they are better candidates for traditional open surgery.

**Box 90.1 Key points in ESMIL.**

- Using an illuminated instrument or the light directed from the laparoscope will improve visualization of the initial dissection and help with establishment of the correct tissue planes during placement of the first two trocars.
- Entry into the correct plane of dissection with scissors facilitates dissection after trocars have been placed.
- Continuous flow of $CO_2$ allows rapid clearing of water vapor or smoke during dissection in the small working space.
- A working pressure of 5 mmHg is sufficient to maintain visualization while avoiding spontaneous infiltration beyond the boundaries of dissection.
- Key landmarks are readily identified and transillumination of the skin facilitates orientation.
- Following the saphenous vein helps with identification of landmarks but as many branches as possible should be preserved to decrease lymph edema in the lower extremity.
- All tissue should be divided with ultrasonic energy or electrocautery to decrease the incidence of lymphatic leak.
- For further details see Video 90.1.

## Preoperative preparation and evaluation

A complete metastatic evaluation should be performed prior to biopsy of the presenting penile lesion or partial penectomy when indicated. The presence of carcinoma of the penis is established with biopsy to determine the diagnosis, extent of invasion, presence of vascular invasion, and grade of the lesion prior to lymphadenectomy. Distant metastatic disease without lymph node involvement is rarely seen. However, distant metastatic spread to bone, brain, liver, and lung should be considered as part of the overall work-up for penile cancer. Computerized tomography of the pelvis and inguinal region can be helpful in determining the presence of large pelvic and inguinal nodes, especially in the obese patient.

Waist-high elastic stockings should be fitted and obtained prior to surgery. Preoperative intravenous antibiotics for skin flora coverage are given 60 minutes prior to the skin incision. A sterile prep of the area is performed in the usual fashion.

## Operating room configuration and patient position

The operating room (OR) is configured so that all of the staff can view the procedure. The surgeon's monitor is placed on the contralateral side of the dissection, near the shoulder and arm of the patient. A second monitor is placed on the opposite side in the case of bilateral dissection or as needed for viewing by the entire team (Figure 90.1).

The patient is placed in a supine position, with the ipsilateral knee flexed and hip abducted. The foot on the side of dissection is secured to the contralateral leg in a unilateral dissection or both feet secured together in the case of a bilateral procedure. A pad placed under the bent knee will help maintain the correct position (Figure 90.2).

## Trocar placement

Before placing the first trocar, the limits of the dissection are marked on the skin to preserve the orientation once the skin is distorted from the insufflation used to create the working space. A line is drawn from the pubic tubercle to the anterior superior iliac crest. The width of the area of dissection is approximately 11–12 cm and the length 15 cm down the medial thigh and 20 cm down the lateral thigh (Figure 90.3).

Trocar placement is the same for the left and right sides. The trocars are placed just outside the delineated area of dissection. Initially, a 2.5 cm incision is made over the saphenous vein 15 cm below the pubic tubercle. It is important to avoid making the incision any larger than 2.5 cm to prevent $CO_2$ escape during the procedure once the trocar is inserted and the subcutaneous cavity insufflated. Sharp, fine scissors are used to develop the plane of dissection elevating the skin from the deep membranous fascia and Scarpa's fascia toward the area of dissection drawn on the skin for as far as the surgeon can see inside the lighted cavity. The laparoscope provides an excellent light source for the initial dissection. A blunt-tipped trocar is placed in the incision to create an airtight seal. The blunt-tipped trocar (USSC, Norwalk, CT, USA) is ideal for this procedure since its unique internal balloon and foam collar create an excellent seal and leaves a very small profile inside the area of dissection. This trocar will become the medial working trocar, and since it is 10 mm it can accommodate a retrieval sac to remove lymph node packets during the procedure. If a large nodal packet is placed in the sac and cannot be

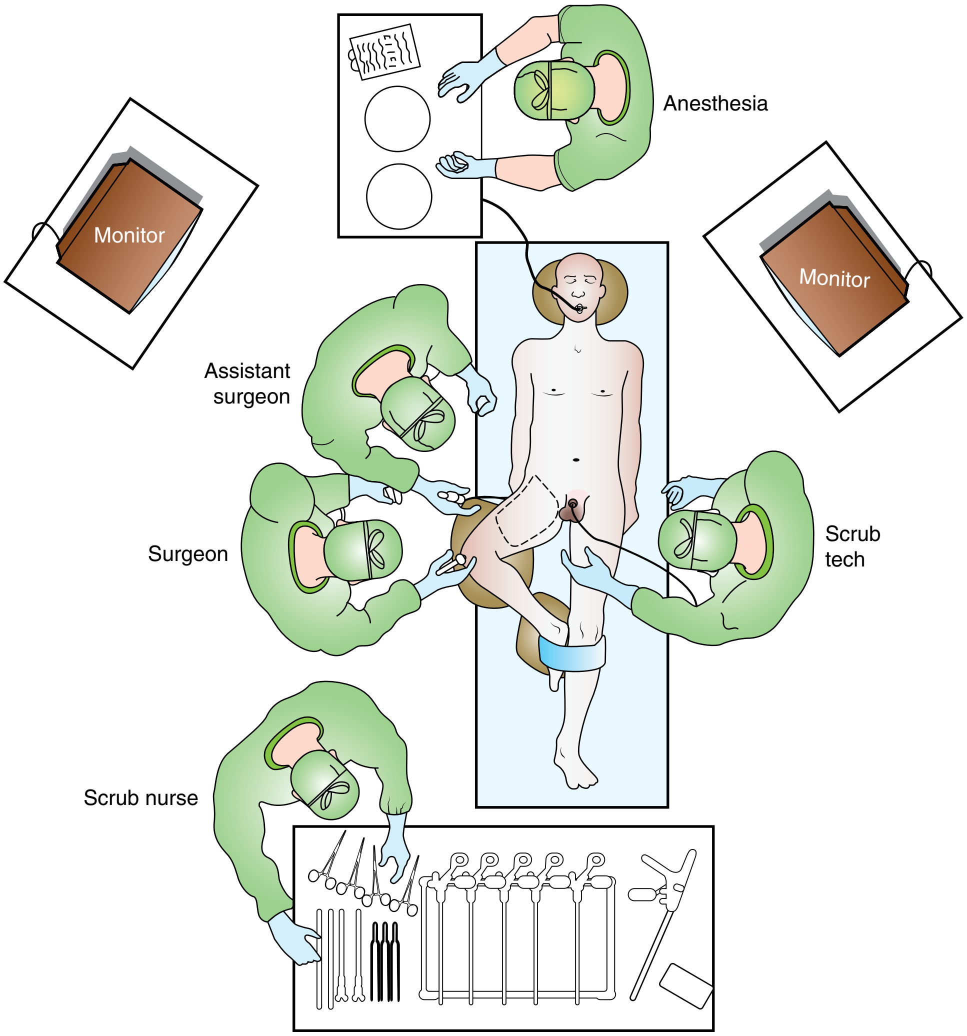

**Figure 90.1** The operating room is configured so that all of the staff can view the procedure. The surgeon's monitor is placed on the contralateral side of the dissection, near the shoulder and arm of the patient. A second monitor is placed on the opposite side in the case of bilateral dissection or as needed for viewing by the entire team.

extracted through the trocar, the balloon on the trocar can be deflated and the packet (secured inside the retrieval bag) can be extracted directly through the incision. In order to prevent seeding the trocar site, fatty and lymphatic tissue specimens should not be extracted directly through the skin incision without being placed inside an extraction sac.

A second 2.5 cm incision is placed outside the area of dissection approximately 16 cm inferior to the middle of the inguinal ligament. Scissors are used to establish the correct plane of dissection toward the first trocar until the two planes of dissection are joined and a second blunt-tipped trocar is placed. The laparoscope is usually placed through the second trocar during the procedure. The working space is insufflated to a pressure of 5 mmHg.

A pair of endoscopic scissors or ultrasonic or bipolar cautery shears are used to dissect the inferior skin margin toward the edge of the surgical field so that the third trocar can be placed. A 5 mm threaded trocar is placed outside the area of dissection approximately 15 cm below the iliac crest (Figure 90.4).

## Procedure

Inguinal lymph nodes are divided into superficial and deep nodes. The superficial nodes are those located anterior to the fascia lata and the deep nodes posterior to the fascia lata. Inguinal lymph nodes dissection is carried out 2 cm above the inguinal ligament superiorly, lateral to the sartorius muscle and medial to the

adductor longus. The superficial nodes are located in four quadrants centered around the saphenofemoral junction: (i) nodes in the area of the superficial circumflex iliac vein; (ii) nodes in the area of the superficial epigastric vein and the superficial external pudendal vein; (iii) nodes located in the inferomedial quadrant around the saphenous vein; and (iv) nodes around the insertion of the superficial circumflex iliac vein and the lateral accessory saphenous vein (Figure 90.5).

The deep inguinal lymph nodes include the most cephalad node, known as the node of Cloquet, which is

located in the area of the femoral vein and the lacunar ligament (Figure 90.6).

The dissection begins above Scarpa's fascia anteriorly, removing the tissue located between the skin and the fascia lata. Early in the dissection, the saphenous vein should be identified and preserved. If possible, it is helpful to identify the borders of dissection medially at the adductor longus and laterally at the sartorius muscle edges. In some patients it can be difficult to identify these landmarks without opening the fascia lata, but the margins marked on the skin will help in the dissection of the superficial nodal tissue. Subcutaneous vessels and saphenous branches can be divided using ultrasonic energy or electrocautery. Lymph node-bearing tissue is dissected from the fascia lata to the fossa ovalis.

As the dissection progresses toward the inguinal ligament, the external ring is identified and the fat and lymphatics in the area of the cord to the base of the penis medially are removed. The lymph node dissection is continued for 3–4 cm superior to the inguinal ligament. Once the nodal tissue and fat are removed from the external oblique and the inguinal ligament, the femoral vessels can be identified inside the femoral sheath.

To gain access to the deep nodes, the fascia lata is opened to the edge of the adductor longus medially and the sartoris muscle laterally. The triangular-shaped lymph packet within the femoral triangle is carefully removed. Opening the femoral sheath down toward the apex of the triangle will reveal the deep lymph nodes. Medial dissection will free the node of Cloquet. Any residual tissue between the femoral artery and vein is removed. Care is taken to prevent injury to the femoral nerve by limiting the lateral dissection to the femoral artery.

If the skin overlying the exposed vessels seems compromised in any way, the sartorius can be mobilized from the anterior superior iliac crest using ultrasonic or bipolar cautery and transferred over the exposed vessels. Three or four size 2-0 polydioxanone sutures are used to attach the sartorius muscle to the inguinal ligament.

At the end of the procedure a 7 mm Jackson–Pratt drain is placed inside the cavity to ensure drainage at the most dependent site of dissection. This can be placed through the 5 mm trocar sit or a new site chosen as needed. The two 10 mm trocar sites are closed with skin adhesive or subcuticular sutures. Once the skin adhesive is dry, a circular bandage is placed around the surgical area and held in place with an elastic bandage for 24 hours.

## Postoperative management

Waist-high elastic stockings are placed and the patient kept on bedrest for 5–7 days with the lower extremities elevated. Low molecular weight heparin or enoxaparin (Lovenox®, Sanofi-Aventis, Bridgewater, NJ, USA) is started after surgery and continued until the patient is fully ambulatory. The subcutaneous drain remains in place until daily output is less than 30 ml.

## Complications

The diagnostic and therapeutic benefits of early inguinal lymphadenectomy should be measured against the potential morbidity associated with the procedure. Patients should be aware of the minor and major postoperative complications associated with this procedure (Box 90.2).

**Box 90.2 Minor and major postoperative complications associated with ESMIL.**

**Minor postoperative complications**

- Local wound debridement in clinics
- Mild to moderate leg edema
- Seroma formation not requiring aspiration
- Minimal skin edge necrosis requiring no therapy
- Scrotal edema

**Major complications**

- Wound infection
- Severe leg edema interfering with ambulation
- Skin flap necrosis requiring skin graft
- Deep venous thrombosis
- Re-exploration or other invasive procedure performed in the OR
- Death

# Laparoscopic and Robotic Retroperitoneal Lymph Node Dissection

*James R. Porter*

*Providence Health and Services Swedish Urology Group, Seattle, WA, USA*

## Introduction

The management of patients with clinical stage I nonseminomatous germ cell tumors (NSGCT) of the testis remains controversial. Treatment options include retroperitoneal lymph node dissection (RPLND), surveillance, and primary chemotherapy. Fortunately, the survival rate is in the range of 95–99% with each treatment modality [1–3]. Therefore, the patient's perception of treatment toxicities and quality of life, without compromising cancer control, has become of paramount importance in decision-making when choosing therapy.

Open RPLND (O-RPLND) has been the standard of care for the surgical management of clinical stage I NSGCT. The approach provides both diagnostic information on the stage of the tumor and is curative in 75–80% of patients with low-volume retroperitoneal disease. With refinements in surgical technique to preserve the postganglionic sympathetic nerves, retrograde ejaculation has been minimized [4]. Nevertheless, there can be significant morbidity from O-RPLND, with associated bowel dysfunction, prolonged hospitalization, and delay in resumption of daily activities and work [5, 6].

The National Cancer Comprehensive Network (NCCN) guidelines for the treatment of stage I NSCGT include surveillance, 1–2 cycles of chemotherapy, or primary RPLND, with surveillance being preferred for low-risk patients [7]. In practice, the role of RPLND as a primary treatment for stage I NSGCT has diminished, and the European Association of Urology Guidelines for NSGCT does not recommend RPLND as a treatment option for even high-risk clinical stage I disease [8]. There are probably several factors contributing to the decline in RPLND, including the significant morbidity associated with O-RPLND. Young men with high-risk NSGCT (evidence of lymphovascular invasion and >50% embryonal cancer) given the choice between two cycles of chemotherapy or an O-RPLND, will usually choose chemotherapy. In addition, as surveillance becomes more prevalent, many urologists may not feel comfortable performing RPLND and chemotherapy then becomes the natural progression of surveillance.

In an attempt to make RPLND less morbid, several investigators have applied minimally invasive techniques to RPLND [9–12]. The effort initially began with laparoscopic RPLND (L-RPLND) and more recently has evolved to include the robot-assisted surgical platform that has gained prevalence with other urologic procedures. This review will highlight the current role of both laparoscopic and robotic RPLND (R-RPLND) in the management of patients with testicular cancer. The goal of this review is to provide a framework for urologists to perform minimally invasive RPLND (MI-RPLND), and at the same time maintain the current standard of cancer care while reducing surgical morbidity for these patients.

## Indications for minimally invasive RPLND

The goal of treating patients with stage I NSGCT should be the timely recognition and treatment of those men with metastatic disease. To avoid overtreatment this goal is best accomplished by the availability of accurate staging information. Of the three treatment options commonly employed for patients with NSGCT, surveillance, chemotherapy, and RPLND, the latter meets these criteria better than the other two options. O-RPLND provides accurate staging information and is curative in 75–80% of patient with stage II disease. MI-RPLND has the potential to provide the same benefits of O-RPLND but with a marked reduction in morbidity. Thus, MI-RPLND

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

Companion website: www.wiley.com/go/smith/textbookofendourology

could provide the diagnostic and therapeutic advantages of O-RPLND but with a marked reduction in morbidity.

The indications for L-RPLND and R-RPLND are the same. Patients with NSGCT found on radical orchiectomy (T1–3) with no evidence of nodal involvement on computed tomography (CT) of the abdomen, no signs of lung involvement on CT of the chest, and negative or normalized tumor markers are appropriate candidates for MI-RPLND. In select patients with small-volume nodal involvement in the abdomen (stage IIa) and predominantly teratoma on orchiectomy, MI-RPLND can be considered depending on the marker status. Patients are counseled regarding all treatment options for NSGCT, including O-RPLND, surveillance, and primary chemotherapy.

As experience has been gained with MI-RPLND, the indications have expanded to patients with residual masses after primary chemotherapy. Masses greater than 1 cm in patients with negative tumor markers may be candidates for MI-RPLND with the caveat that larger masses (N3) and tumors involving renal hilum may be better addressed with O-RPLND.

Contraindications to MI-RPLND include pure seminoma, patients with elevated tumor markers despite negative nodes on CT scan and patients who have had prior abdominal radiation. Relative contraindications include extreme obesity (body mass index >40), prior episodes of peritonitis, and coagulopathy. Patients with prior abdominal surgeries can usually undergo successful MI-RPLND after takedown of adhesions.

## Patient preparation

Patients being considered for MI-RPLND should undergo complete staging of the disease with radiographic imaging of the chest and abdomen, and tumor marker assessment including alpha-fetoprotein, beta-human chorionic gonadotropin, and lactate dehydrogenase. If there is a delay of more than six weeks from the initial CT scan of the abdomen to the time of surgery, it is prudent to repeat the CT to look for evidence of nodal enlargement as this may affect the clinical stage of the disease and the operative plan. Patients should be counseled that there is a possibility of conversion to open surgery due to vascular or bowel injury and this should be clearly stated in the informed consent. This is especially important in patients undergoing a postchemotherapy MI-RPLND, where there can be significant fibrosis and scarring between the tumor and great vessels. The patient should also be informed of the possibility of nephrectomy as this is sometimes necessary due to tumor involvement of the renal hilum. They should be aware of the risk of blood transfusion. We routinely counsel patients that they will be on a low-fat diet (20 g of fat per day) for two weeks after the procedure to decrease the risk of developing chylous ascites that may require bowel rest with total parenteral nutrition and reoperation if it does not resolve. Finally, we encourage patients to bank sperm prior to surgery in the event of retrograde ejaculation.

To decrease the size of the intestines and provide more working space for MI-RPLND, patients are asked to undergo a modified bowel preparation the day prior to surgery with a clear liquid diet and magnesium citrate orally. We request that patients avoid platelet inhibitors such as aspirin and nonsteroidal anti-inflammatory medications for seven days prior to the procedure. Patients are typed and crossed for blood in the event of acute hemorrhage during the procedure.

## Preoperative preparation

### Anesthesia and patient position

Patients undergoing both L-RPLND and R-RPLND require general endotracheal anesthesia with continuous attention by the anesthesiologist to deep paralysis to maintain adequate pneumoperitoneum. A Foley catheter and orogastric tube are placed prior to positioning the patient to decompress the bladder and stomach and decrease the risk of injury during port placement as well as to provide more room in the peritoneal space for the procedure. Sequential compression stockings are placed on the lower extremities and a cephalosporin antibiotic is administered just prior to making the incision.

For L-RPLND and R-RPLND using the lateral approach patients are placed in a 60° modified flank position with the side of prior orchiectomy up (Figure 91.1). The patients are well padded on a gel pad and the legs are supported with pillows. The arms are placed on an arm board with pillows placed between the arms, although we sometime place the arms in a “prayer” position for patients undergoing R-RPLND. For R-RPLND using the supine approach, patients are placed supine with the arms padded and tucked by the sides and the legs are straight with sequential compression stockings (Figure 91.2). Because the patient is placed in a slight Trendelenburg position, a full body gel pad is placed between the patient and operating table to prevent patient movement. As with the lateral position, Foley catheter, orogastric tube, and pre-incision antibiotics are employed.

### Operating room setup and equipment: L-RPLND

L-RPLND is routinely accomplished with two assistants and a scrub nurse helping the primary surgeon (Figure 91.3). The room configuration for L-RPLND

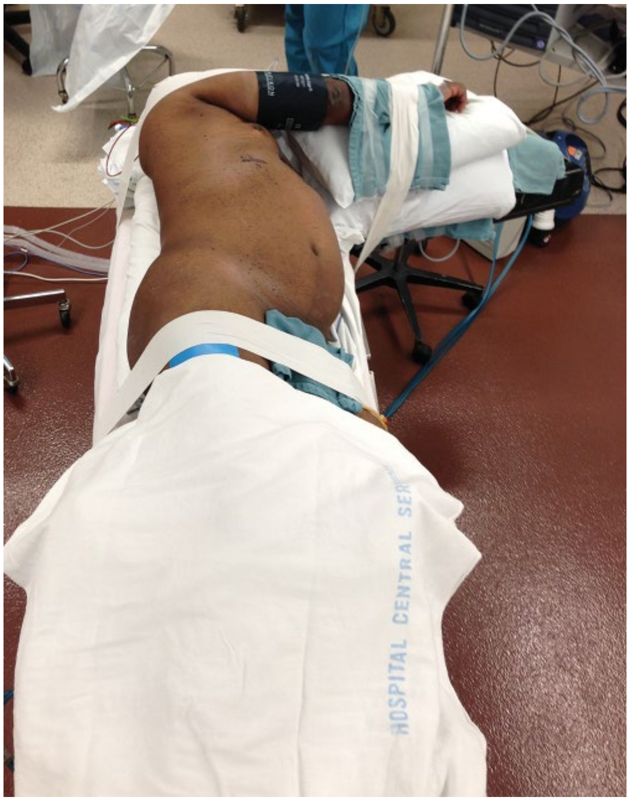

**Figure 91.1** Lateral modified flank position for minimally invasive retroperitoneal lymph node dissection with arms on arm board.

requires the primary surgeon and the first assistant to be standing on the side contralateral to the side of prior orchiectomy. The second assistant and scrub nurse stand on the side opposite the primary surgeon and first assistant. The anesthesia team is at the patient's head with full access to the airway and face. Video monitors are located on both sides of the patient to allow all involved personal to have an optimum view of the operative field. The first assistant's primary role is to hold the endoscope and maintain a steady operative view. The second assistant usually controls a grasping device or retractor to provide tissue exposure.

Laparoscopic instruments routinely used during L-RPLND include endoscopic scissors, graspers, clip appliers, and blunt dissectors. A 30° endoscope is usually used. In the event of vascular injury, laparoscopic needle drivers should be available along with a "rescue stitch" to allow rapid control of bleeding if this is encountered. A rescue stitch in our experience is a 4-0 polypropelene suture cut to 12 cm with a polymer clip on the end of the suture opposite the needle. This allows multiple throws of the needle without the need to tie the suture, although the clip can be removed and the sutured tied once bleeding is controlled if this is the surgeon's preference. Lymph nodes are removed with the aid of an endoscopic retrieval bag that decreases the risk of potential tumor cells coming into contract with the abdominal wall or an extraction port. Hemostatic agents are used at the end of the procedure to aid in the sealing of lymphatic changes that

may remain open after lymph node removal. As with any laparoscopic procedure an open laparotomy set is in the room, opened and prepared in the event of rapid conversion to open surgery.

## Operating room setup and equipment: R-RPLND

The robotic setup will depend on whether the lateral or supine approach is used or whether the da Vinci® Si or Xi (Intuitive Surgical, Inc., Sunnyvale, CA, USA) is employed. For the lateral approach with the da Vinci Si the robot is docked over the patient's back on the side of the bed ipsilateral to the orchiectomy (Figure 91.4). The bedside assist and scrub nurse are on the side opposite the robot and the primary surgeon resides at the surgeon's console. The anesthesia team is again located at the patient's head. A second assistant is not routinely used during R-RPLND. For the supine approach using the da Vinci Si, the robot is docked over the patient's left shoulder after the patient is placed in a 15–20° Trendelenburg position (Figure 91.5). The bedside assistant stands on the patient's right directed toward the head of the patient and the scrub nurse is usually on the

same side. The anesthesiologist will be on the right side of the patient's head opposite the robot. The patient side vision cart holds the insufflator, electrosurgical unit, light source, and accessory energy components and can be placed in the optimum position depending on room size and configuration specific to the room.

The da Vinci Xi is designed to allow docking from any position due to the presence of a rotating boom. This permits the robot to be brought in from any direction depending on the side of the dissection and thereby simplifies patient position and room configuration. It is also designed to allow extended reach of the robotic arms and allows multi-quadrant access in the abdomen and is ideal for RPLND. Given these advantages, the da Vinci Xi is our preferred platform for R-RPLND and we have abandoned the lateral position and da Vinci Si for R-RPLND.

For a left-sided R-RPLND using the da Vinci Xi the patient is placed in the Trendelenburg position and the robot can be brought in on the patient's left side, right side or over the foot of the patient as shown in Figure 91.6.

The bedside assistant stands on the right side directed up toward the head and the scrub nurse is on the patient's left. The mirror image configuration is used for a right-sided R-RPLND.

The instrumentation used for R-RPLND is much the same irrespective of the approach or which model robot used. The monopolar scissors are used in the right robotic arm, fenestrated bipolar in the left arm, and atraumatic grasper in the fourth robotic arm. For the lateral approach with the da Vinci Si, a 0° lens is used in the lateral camera position. For the supine approach with da Vinci Si or Xi, a 0° lens is used initially during exposure of the retroperitoneum and then switched to a 30° down lens during dissection of the lymph nodes. Other robotic instruments routinely used during R-RPLND include the robotic needle drivers and the robotic clip applier. The robotic clip applier is an important aid for R-RPLND as it allows clips to be applied in tight spaces and with angles that cannot be accomplished by the bedside assistant. The bedside assistant uses a suction-irrigation device throughout most of the procedure, but may be called upon to apply clips with a laparoscopic clip applier. Similar to the laparoscopic procedure we have a "rescue stitch" prepared and ready for vascular control. Lymph nodes are extracted with an endoscopic retrieval sac and hemostatic agents are applied to the dissection bed to decrease the risk of lymphatic leakage.

## Technique

### Access and port placement: L-RPLND

Once the patient has been sterilely prepped and draped, pneumoperitoneum is established by either an open technique using a Hasson port or a closed technique using a Veress needle. If a Veress needle is used this is usually placed in the midclavicular line below the ipsilateral costal margin to avoid the midline great vessels. For a right-sided L-RPLND a five-port configuration is used as shown in Figure 91.7. A 12 mm camera port is placed in the midline midway between the xiphoid and umbilicus. A second 12 mm port is used for the right hand to allow clip appliers and possibly a stapling device if necessary. The remaining ports are 5 mm located in the mid rectus muscle for the left-hand instruments, laterally for assistance with retraction, and just below the xiphoid for liver retraction. The key for L-RPLND is to move the ports medial relative to laparoscopic renal procedures to allow access to the midline structures such as the vena cava and aorta. A four-port configuration is used for a left-sided L-RPLND as there is no need for a liver retractor.

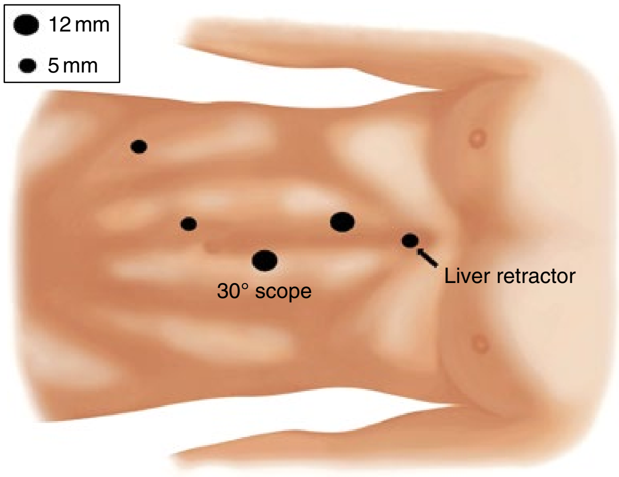

**Figure 91.7** Right laparoscopic retroperitoneal lymph node dissection port configuration.

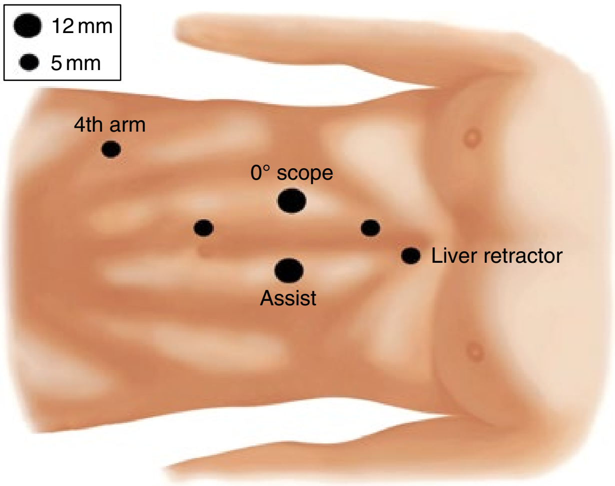

**Figure 91.8** Right robotic retroperitoneal lymph node dissection lateral approach port configuration with da Vinci Si.

### Access and port placement: R-RPLND

Access for R-RPLND is the same as for L-RPLND and port placement varies depending on approach or which model da Vinci robot is being used. For a right lateral R-RPLND using the da Vinci Si a six-port configuration is used with the 12 mm camera port placed midway between the umbilicus and xiphoid in the mid rectus muscle (Figure 91.8). In contrast to the lateral approach for L-RPLND, the camera for R-RPLND is placed lateral to the other ports to decrease external arm collision and allow more room for the bedside assistant. The left and right robotic arms are placed near the midline and the assistant is placed just medial to the line created by these two ports. The fourth robotic arm is placed laterally near the ipsilateral anterior superior iliac spine and is essential for R-RPLND to allow retraction and to facilitate dissection behind the great vessels. A 5 mm

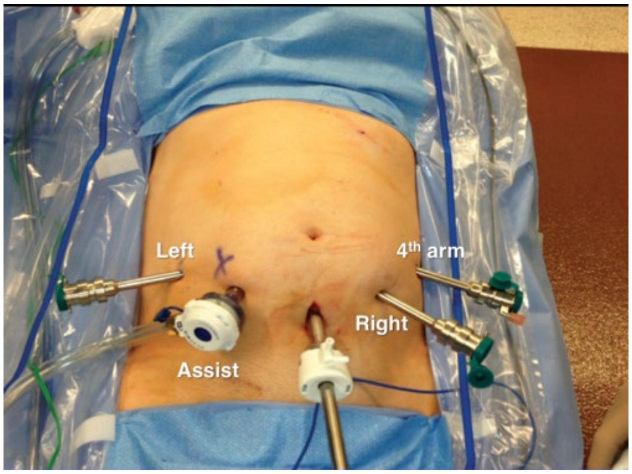

**Figure 91.9** Supine robotic retroperitoneal lymph node dissection port configuration with da Vinci Si.

subxiphoid port is placed to allow retraction of the liver. The mirror image port configuration for left-sided R-RPLND is performed with the exception of the liver retractor, which is not necessary on the left side.

For supine R-RPLND the port configuration depends on which model da Vinci is being employed. A five-port fan configuration is utilized for da Vinci Si with the 12 mm camera port in the midline approximately 4 cm below the umbilicus (Figure 91.9). The 8 mm right robotic arm and fourth arm are placed on the patient's left and the 12 mm assistant port is placed between the camera and the 8 mm left robotic port. This port configuration is used for both left- and right-sided supine R-RPLND using the da Vinci Si.

The robotic arms on the da Vinci Xi are designed to avoid external arm conflict by placing the ports in a linear configuration without the need for port offset as commonly employed with the da Vinci Si. The right-sided da Vinci Xi port configuration is shown in Figure 91.10a. The ports are placed linear at a slight angle to allow room for the assistant in the left lower quadrant. The camera port and the right robotic arm port are placed on either side of the medial umbilical ligaments. The ports are placed approximately 6–7 cm apart to allow freedom of movement and avoid conflict. The robot is docked from the right side and the 30° lens is used after exposure is created. The left-sided da Vinci Xi approach is shown in Figure 91.10b. For a full bilateral approach with the da Vinci Xi, as in the setting of postchemotherapy RPLND, the linear port configuration is not angled but placed at a right angle to the midline to allow access to both the right and left distal ureters.

## Boundaries of dissection: L-RPLND

The right-sided template dissection performed during L-RPLND begins with complete mobilization of the right colon and duodenum, exposing the retroperitoneum and great vessels. The gonadal vessels are clipped and dissected down to the internal inguinal ring where the entire cord is removed along with cord stump as indicated by retained suture. The renal pedicle establishes the upper limit of dissection while the inferior mesenteric artery is the lower limit of resection medially. The lower limit of dissection laterally is the crossing of the ureter over the right common iliac artery. The modified unilateral template dissection on the right side includes removal of the precaval, paracaval, retrocaval, interaortacaval, and preaortic node packages with extension to the left paraaortic nodes. The postganglionic sympathetic nerve fibers are identified coming off the sympathetic chain and are traced under the inferior vena cava on their way to the hypogastric plexus. These fibers are preserved within the template. The split and roll technique is used

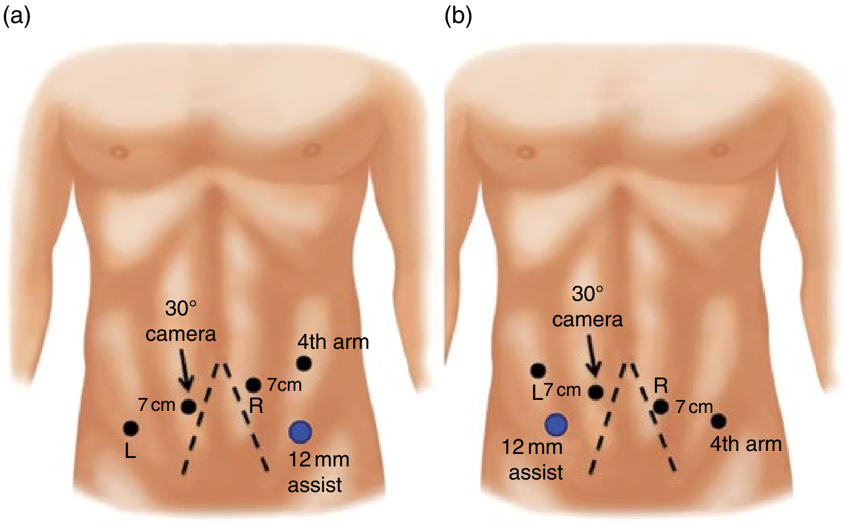

**Figure 91.10** Right (a) and left (b) supine robotic retroperitoneal lymph node dissection port configuration with da Vinci Xi. For bilateral dissection the linear port array is placed horizontally below umbilicus.

to remove retrocaval nodal tissue, which includes nodal tissue posterior to lumbar vessels. Care is taken to clip all lymphatic channels to prevent lymph leakage, especially the lymphatic channels crossing over the left renal vein. For the left-sided L-RPLND the descending colon is mobilized from the splenic flexure to the iliac vessels and medially to expose the great vessels. The gonadal vessels are once again mobilized and clipped at their proximal origin and dissected down into pelvis to remove the entire cord stump. Dissection of the paraaortic lymph nodes begins at the renal hilum and extends to the where the left ureter crosses over the common iliac artery. The postganglionic fibers on the left side are not as large as the right and can be difficult to identify and maintain. The preaortic and interaortocaval nodes are dissected from the renal hilum to the inferior mesenteric artery, which is spared.

Excised tissues are removed in organ entrapment bags and sent for immediate frozen section analysis. Patients with positive lymph nodes and stage IIA or stage IIB disease are repositioned for contralateral L-RPLND with nerve sparing. In patients found at surgery to have stage IIC disease, the procedure is terminated after unilateral dissection and the patient is scheduled for post-RPLND chemotherapy.

### Boundaries of dissection: R-RPLND

The dissection performed for the lateral robotic approach is the same as described for L-RPLND, with the need to reposition and redrape the patient if positive nodes are found on frozen section. For supine R-RPLND the dissection is the same with the da Vinci Si or Xi but is modified depending on the stage of the patient. To begin the dissection the retroperitoneum is exposed by incising the posterior peritoneum medial to the cecum and extending this incision toward the ligament of Trietz. The cut edge of the posterior peritoneum is sutured to the right side of the anterior abdominal wall to provide exposure of the great vessels and retroperitoneum. The left side of the cut edge of the posterior peritoneum is likewise sutured to the left side of the anterior abdominal wall, creating a hammock-like barrier preventing the small bowel from falling into the retroperitoneum. The combination of the suspension sutures and the Trendelenburg position provides excellent exposure. Although the suspension sutures provide the distal exposure of the retroperitoneum, the fourth robotic arm, using an atraumatic grasper, is used to retract the duodenum proximally and create proximal exposure.

Patients with clinical stage I NSGCT undergo a unilateral template dissection with nerve sparing as described for L-RPLND. Lymph nodes are sent for frozen section analysis and, if positive, a full bilateral dissection is performed. For patients with postchemotherapy residual masses, a full bilateral dissection with nerve sparing is performed, including complete removal of the ipsilateral spermatic cord. With the da Vinci Si, this is accomplished by repositioning the robot parallel to the ipsilateral leg, providing access to the spermatic cord and internal inguinal ring. Dissection is then carried out caudally, excising the spermatic cord out of the internal inguinal ring until the remnant suture from radical orchiectomy is removed. With the da Vinci Xi, the spermatic cord is fully accessible without the need to reposition the robot.

## Results

The experience with MI-RPLND began with L-RPLND as case reports and then larger single and multi-institutional series. The most extensive analysis of L-RPLND was a review article authored by Rassweiler et al. that evaluated over 800 patients in 34 publications [13]. The majority of the patients underwent a modified template dissection and the mean number of lymph nodes removed across all studies was 16. Operative times were longer for L-RPLND as compared to O-RPLND, 208 versus 186 minutes, and complications for L-RPLND were 15.6% with a 1.7% re-intervention rate, both of which are comparable to O-RPLND. Oncologic outcomes for L-RPLND were determined from five studies with 557 patients and a mean follow-up of 63 months. The vast majority of patients (126 out of 140) with positive nodes after L-RPLND received chemotherapy, and of the 14 patients who were followed, 2 patients had recurrences and were successfully salvaged with chemotherapy. Despite the large number of patients, there were no infield retroperitoneal recurrences in the area of the template dissection, although 1.4% of patients had recurrences out of the area of dissection and 3.3% of patients developed distant recurrences. There was one port site recurrence noted. Compared with O-RPLND, there was no difference in relapse rates, percentage of patients receiving chemotherapy (29% vs. 31%), rate of salvage surgery (1.2% vs. 1.5%), and patients with no evidence of disease (NED; 100% vs. 99.7%). The authors concluded that L-RPLND offers accurate staging and long-term outcomes similar to O-RPLND and that further studies should be performed to determine the therapeutic benefit of L-RPLND in patients with low-volume retroperitoneal disease.

A multi-institutional retrospective review of L-RPLND from four centers of excellence was reported by Nielsen et al. [14]. The study group included 120 patients with clinical stage I NSGCT who underwent primary RPLND employing a template dissection. Pathologically, 74 patients had stage I disease and 46 had positive lymph nodes with stage II disease. Median lymph node count was 20 with a median count of 22 for patients with negative lymph nodes and 15.5 for patients with positive lymph nodes. Thirty-six of 46 (78%) with stage II disease received chemotherapy while 10 patients were observed. Of the 10 stage II patients observed, 2 had recurrence of disease, both at eight months after surgery. Both were successfully treated with chemotherapy. Of the 74 pathological stage I patients, 7 (9%) developed recurrence at a mean follow-up of 36.4 months, with 4 pulmonary, 2 pelvic, and 1 marker recurrence. All patients were salvaged with chemotherapy and surgery was performed for the patients with pelvic recurrence. With a median follow-up of 29 months, there was no evidence of retroperitoneal recurrence in the region of dissection. The authors concluded that in experienced hands, L-RPLND can be performed safely and with outcomes comparable to O-RPLND based on intermediate-term follow-up.

The most recent experience with primary L-RPLND for clinical stage I NSGCT was published by Hyams et al. from Johns Hopkins who reported on 91 patients over a 15-year period [15]. The majority of patients had high-risk features, with 66% having lymphovascular invasion and 60% with greater than 40% embryonal carcinoma in the orchiectomy specimen. The median blood loss was 200 ml and two patients received transfusions. Operative times were not reported. There were 4 (4.3%) open conversions and 4 (4.3%) intraoperative complications, including a renal vein injury and an aortic injury that were converted to open surgery. The remaining two intraoperative complications were a renal artery injury and a serosal injury both of which were repaired laparoscopically. The mean length of stay was 2.1 days and there were 9 postoperative complications, 3 of which were related to lymphatic fluid leakage. Four patients experienced retrograde ejaculation. The mean lymph node count was 26.1 and 28 out of 91 patients had positive lymph nodes. Seven of these patients were pN2 status and received chemotherapy, while the remaining 21 were pN1. Fourteen of the pN1 patients elected to receive postoperative chemotherapy and 7 were followed with no evidence of recurrence. At a median follow-up of 38 months, no patient demonstrated a retroperitoneal recurrence and 5 of the pN0 patients developed systemic recurrence and were treated with chemotherapy.

Although there a few select centers still performing L-RPLND, the majority of MI-RPLND has evolved to the robotic approach due to improved visibility, better access to the retroperitoneum, and more comfort in controlling bleeding encountered during dissection around the great vessels. The first report of R-RPLND was presented by Davol et al. and demonstrated that it was technically feasible [16]. A case series of three patients with NSGCT undergoing primary R-RPLND was reported by Williams et al. in 2011 [17]. Patients were placed in the lateral position and the technique described was an extension of the laparoscopic approach using the robot. All three patients underwent unilateral template dissections without complications and no positive lymph nodes.

A series demonstrating the supine approach for R-RPLND was recently published by Cheney et al. from the Mayo Clinic [18]. They reported on 18 patients, 9 with primary testicular cancer, 8 with residual masses after chemotherapy, and 1 with paratesticular rhabdomyosarcoma. The supine approach was successful in 15 of the 18 patients with open conversion performed for hemorrhage, poor exposure, and robotic malfunction in three cases. Mean operative time was 311 minutes for primary R-RPLND and 369 minutes for postchemotherapy R-RPLND ($P = 0.03$). Mean estimated blood loss was 100 ml for primary R-RPLND and 313 ml for the postchemotherapy group ($P = 0.13$). Mean length of stay was 2.4 days and there were three minor (Clavien II) complications (17%). Mean lymph node count was 20 and lymph nodes were positive in 8 of 18 patients (44%), including 5 of 8 patients with postchemotherapy tumors and 3 of 10 patients undergoing primary R-RPLND. No patient received adjuvant chemotherapy, and at a mean follow-up of 22 months, there were no retroperitoneal recurrences, although two patients required salvage chemotherapy for pulmonary recurrence. This study highlighted the utility of the supine approach for R-RPLND and demonstrated that a full bilateral dissection could be performed without the need for reprepping and redraping the patient.

Our group recently reviewed our experience with R-RPLND using both the lateral and supine approaches [19]. Our initial experience was an extension of our laparoscopic procedure and we quickly recognized that the robotic platform offered several advantages over the laparoscopic approach. The advantages include 3D vision with improved visibility, enhanced instrument dexterity, and most importantly, better control of major vascular bleeding. A major limitation of the lateral approach was the inability to perform a full bilateral dissection in the event of positive nodes or in patients with postchemotherapy residual masses. The supine approach using the da Vinci robot addresses this issue and allows a full bilateral dissection without redocking or repositioning the patient. It also permits a superior view of the postganglionic sympathetic fibers in those patients undergoing nerve-sparing R-RPLND. Our experience includes 19 patients who underwent 20 procedures with 11 clinical stage I, 6 clinical stage II, and 3 clinical stage III patients. There were 16 primary and 4 postchemotherapy procedures with 11 lateral and 9 supine approaches. Median operative time for the group was 293 minutes, but was 259.7 minutes for unilateral dissections and 313 minutes for bilateral procedures. Median estimated blood loss was 50 ml and no patient required transfusion or conversion for bleeding. The median length of stay was 1 day with 14/20 (70%) of patients being discharged in less than 24 hours. Median lymph node count was 19.5. Eleven patients had pathologic stage I disease and 8 patients had pathologic stage II. One of the 8 with retroperitoneal disease had clinical stage I, 6 had clinical stage II, and 1 had clinical stage III disease preoperatively. Teratoma was found in 3 patients: 2 with clinical stage II disease and 1 with clinical stage III disease. There has been no evidence of recurrence in these patients. Embryonal carcinoma was found in 5 patients, 4 of whom had pathologic stage IIA, and 1 pathologic stage IIC disease. Two of these 5 patients received chemotherapy: 1 with pathologic stage IIC disease, and 1 with pathologic stage IIA disease who was followed and found to have a lung recurrence at four months after surgery. Three patients with pathologic stage IIA disease did not receive chemotherapy and have been followed expectantly; they have not required systemic therapy at follow-up of 46, 47, and 91 months. There has been no evidence of retroperitoneal disease recurrence in any patient in the series at a median follow-up of 49 months. There was one complication in the series. A ureteral transection occurred due to tumor involvement during a left-sided R-RPLND in clinical stage II patient. The ureter was repaired over a stent and remains patent after stent removal. Two patients who underwent bilateral R-RPLND suffered ejaculatory dysfunction.

A recent comparative analysis between L-RPLND and R-RPLND was reported by Harris et al. in *BJU International* in 2015 [20]. They compared 21 L-RPLND with 16 R-RPLND performed by a single surgeon. The series represented a mature experience with L-RPLND as compared to the early learning curve with R-RPLND. Despite this difference in experience, the outcomes for the two MI-RPLND techniques were essentially the same. The R-RPLND operative time was 270 minutes versus 294 minutes for L-RPLND, representing a difference of 24 minutes that was not statistically significant. Median estimated blood loss was 125 ml for L-RPLND and 75 ml for R-RPLND ($P = 0.16$). Median lymph node yield was 22 for L-RPLND and 30 for R-RPLND ($P = 0.13$). There were 2 (9.5%) postoperative complications in the L-RPLND group and 1 (6.3%) complication in the R-RPLND cohort. Follow-up for both groups was too short to make any meaningful statements about oncologic outcomes. The authors concluded that R-RPLND appears comparable to L-RPLND but at this stage it is unclear whether R-RPLND offers any tangible benefits over standard laparoscopy.

## Conclusions

MI-RPLND has undergone an evolution with regard to both technique and intent of the procedure. Initially, L-RPLND was performed as a staging procedure to direct adjuvant treatment in those patients with positive nodes, but with growing experience the procedure was carried out with therapeutic intent. To date, there have been many young men with pathologic stage II disease who have been cured with L-RPLND and have avoided the sequelae of chemotherapy including neuropathy, cardiovascular disease, infertility, and secondary cancers. There have been no recurrences reported in the retroperitoneum when L-RPLND was performed with care to remove the retrocaval and retroaortic tissues. Multiple studies have demonstrated that L-RPLND is feasible, safe, and reproducible, with reduced surgical morbidity compared to O-RPLND.

The application of robotics to RPLND has addressed the major hurdle of L-RPLND – the control of major vascular bleeding. In addition, the robotic platform has facilitated the development of the bilateral approach in patients with positive lymph nodes and opened the door for the safe application of minimally invasive surgery to postchemotherapy masses. R-RPLND is the future of MI-RPLND. There will be and should be continued scrutiny of MI-RPLND, as the current standards set by O-RPLND need to be adhered to and not compromised in the effort to reduce patient morbidity.

# Laparoscopic Radical Nephrectomy

*Simpa S. Salami*

*Department of Urology, University of Michigan, Ann Arbor, MI, USA*

## Introduction

Laparoscopic surgery is a standard technique for the management of benign and malignant renal conditions. The first (pure) laparoscopic radical nephrectomy (LRN) was performed in 1991 by Clayman et al. [1]. Since its inception, modifications have been made to the technique to improve perioperative, short- and long-term functional and oncological outcomes. These modifications include retroperitoneal approach, hand-assisted and robotic-assisted techniques [2, 3]. The introduction of robot-assisted laparoscopic surgery was rapidly adopted by urologists largely because of the improved learning curve. Although laparoscopic techniques have evolved, allowing urologic surgeons to perform minimally invasive partial nephrectomies for smaller yet complex renal masses (see Chapter 93), LRN remains the gold standard for clinically localized renal masses. This chapter will review the indications, techniques, and results for laparoscopic radical nephrectomy, including hand- and robotic-assisted approaches.

## Indications for and contraindications to laparoscopic radical nephrectomy

The most common indication for radical nephrectomy is kidney cancer, which accounts for 3–5% of all adult malignancies [4]. Most clinical practice guidelines, including the American Urological Association and European Association of Urology guidelines, recommend radical nephrectomy (RN; surgical removal of the entire kidney, including Gerota's fascia, ± the ipsilateral adrenal gland) in patients with clinical stage T2, T3, or T4 renal cancer or in patients with multifocal ipsilateral renal masses without genetic predisposition [5, 6]. Although nephron-sparing surgery is recommended for T1 renal masses, RN may be performed in certain situations such as patient's preference or surgeon's inexperience (see Chapter 93). Whenever possible, however, partial nephrectomy should be performed for T1a renal masses [7]. The increased risk of cardiovascular mortality associated with decreased glomerular filtration rate (GFR) has been well documented [8]. This reduction in GFR has also been demonstrated in those who undergo radical nephrectomy for T1b lesions when compared to those who underwent partial nephrectomy [9]. Decreasing the risks associated with a compromised GFR, coupled with the sound oncologic data for nephron-sparing surgery, has led to the recommendation for partial nephrectomy for complex or T1b renal masses [10–14]. If not amenable to minimally invasive techniques, an open partial nephrectomy should be considered [15].

LRN with or without hand or robotic assistance can be utilized for clinically localized T2 disease. Recently, these techniques have been successfully modified and popularized for advanced T3 or T4 disease [16–19]. Finally, LRN or RLRN may also be used in the setting of cytoreductive nephrectomy to reduce the overall tumor burden when the metastatic disease burden is smaller in size than tumor burden within the kidney [20].

Contraindications are the same as for open radical nephrectomy and those specific to laparoscopy in general. Patients with significant coagulopathy or comorbidities that preclude them from undergoing general anesthesia or major surgery should not be subjected to LRN. LRN is also contraindicated in patients with inability to tolerate pneumoperitoneum, such as in chronic obstructive pulmonary disease (COPD) or morbid obesity. Although previous surgery at the same site has demonstrated increased operative time and hospital stay, it is not an absolute contraindication to performing laparoscopy [21]. Previous abdominal surgery may increase risk of either

complications or need for conversion to open surgery. Recent reports have been published regarding the minimally invasive management of a renal vein, inferior vena cava (IVC), or atrial thrombus, but this is limited and should only be performed in highly experienced centers [22]. Finally, advanced age is not an absolute contraindication to LRN [23].

## Preoperative evaluation and patient preparation

In general terms, the preoperative work-up for a patient with a renal mass is no different for an LRN than that for an open radical nephrectomy (see Chapter 77 for details on patient preparation). Briefly, this includes a detailed history and physical examination, a complete blood count, serum electrolytes, coagulation profile, calcium, and alkaline phosphatase. A chest X-ray or chest computed tomography (CT) scan is required to screen for pulmonary metastases. A bone scan is unnecessary in the absence of bone pain or an elevated alkaline phosphatase. A head CT scan is indicated in the presence of neurological symptoms. If the serum creatinine is elevated, a 24-hour urine creatinine level and possibly a MAG3 or DMSA renal scan may be needed to assess differential renal function. Usually the patient presents with abdominal imaging demonstrating a renal mass. If abdominal imaging is inadequate, a three-phase CT or magnetic resonance imaging (MRI) is required to document enhancement of the renal mass. Abdominal imaging may also inform operative planning and approach if multiple renal arteries are identified, for example. If there is concern for a renal vein or caval thrombus, an MR venogram should be obtained. Finally, although the evidence for lymphadenectomy in renal cell carcinoma remains inconclusive, careful attention should be paid on imaging to regional and retroperitoneal lymphadenopathy. Despite the European Organization for Research and Treatment of Cancer (EORTC) trial demonstrating no improvement in survival in those who underwent lymphadenectomy for localized renal cell carcinoma [24], others have demonstrated improved staging capability [25–27] and, in certain situations, improved survival with lymph node dissection for clinically detected lymphadenopathy [28]. The patient is kept nil per os after midnight the evening before surgery. The use of a mechanical bowel preparation is optional. Some prefer to use a bowel preparation in order to decompress the colon and small bowel for improved visualization and working space within the abdomen. A single dose of an antibiotic agent is given 30–60 minutes prior to the first incision to cover skin flora. Venous sequential compression devices are placed around the calves of the patient and initiated prior to the induction of general anesthesia. A prophylactic dose of subcutaneous heparin may be administered.

## Laparoscopic transperitoneal nephrectomy

### Patient positioning

The patient is placed in the supine position upon arrival in the operating room. After induction of general endotracheal anesthesia, an orogastric tube and bladder catheter are inserted to decompress the stomach and bladder respectively. The location of the extraction site, usually a Pfannenstiel or an infra-umbilical midline incision, is marked on the patient's skin to ensure a straight incision after the patient is positioned. The patient is then carefully placed in a modified lateral decubitus position, angled at approximately 30° from the ground. The patient's flank overlays the kidney rest, an axillary role is placed, and an additional roll is placed longitudinally along the patient's back to support the thoracolumbar spine. The two legs are kept straight with a pillow or other padding placed behind the knees for support. Thick (silk or cloth) tape is used to secure the patient to the table (with paddings) at several points in order to prevent the patient from sliding off the table during the procedure should the table require rotating (Figure 92.1). Finally, the abdomen is prepped and draped in a sterile fashion, along with the corresponding flank in case the need arises to convert to an open procedure.

### Access

This can be achieved in a variety of ways, including but not limited to the Veress needle or Hasson cut-down technique, depending on the experience or comfort of the surgeon. The Hasson cut-down technique is preferred by some surgeons, especially in cases of previous abdominal surgeries, although the utilization of Veress needle access is documented to be safe in this patient group as well [15]. The abdomen is insufflated to a pressure of 15–20 mmHg. Once sufficiently insufflated, a 10 mm reusable screw or a 12 mm disposable trocar is placed into the abdomen at the level of the umbilicus for the camera. The position of this trocar may be shifted proximal or lateral depending on the abdominal girth after sufficient pneumoperitoneum is achieved. A 0° or 30° lens is utilized depending on surgeon's preference. The abdominal contents are inspected for any injury during access or from introduction of the first trocar. A second 12 mm trocar is placed at the level of the

umbilicus in the anterior clavicular line. A valveless (AirSeal®, ConMed, Utica, NY, USA) trocar system is preferred by some surgeons at this site, because of the documented stability of insufflation pressure during aggressive suctioning and reduction in $CO_2$ consumption [29, 30]. A third, 5 mm trocar is placed approximately 8 cm cephalad to the umbilical trocar in the midline. For a right nephrectomy, an additional 5 mm port may be placed inferior to the subxiphoid process to assist with liver retraction (Figure 92.2). Again, if the patient is obese, all respective port positions may need to be placed laterally and superiorly in order to account for abdominal wall distortion. Further, for large renal masses, a 12 mm port should be considered in place of the 5 mm port to allow for maximum versatility in passing a greater variety of instruments through any port location. Finally, if an additional port is needed for retraction, an ideal placement is in the previously marked Pfannenstiel or infra-umbilical midline incision line. At the completion of the case, the extra port incision is extended and used to extract the specimen.

## Procedure

The white line of Toldt is incised sharply. If electrocautery is utilized for this incision, care must be taken to avoid the risk of bowel injury from thermal spread. A plane is developed between the posterior mesenteric and anterior perirenal fat using a combination of blunt and sharp dissection. The respective colon is mobilized medially from the iliac vessels to the respective hepatic or splenic flexure. For a right nephrectomy, the hepatic flexure is released by dividing the renocolic ligament. This allows for further medial mobilization of the colon. The duodenum is mobilized using sharp dissection. Minimal use of blunt dissection is encouraged around the duodenum to avoid inadvertent serosal injuries. Duodenal mobilization is completed after gaining adequate exposure to the IVC (also referred to as a Kocher maneuver). In the case of a left nephrectomy, the left colon is mobilized similarly with a combination of blunt and sharp dissection. The splenorenal ligament and splenophrenic attachments are divided in order to mobilize the spleen medially, en bloc with the splenic flexure, which provides medial reflection of the tail of the pancreas. This maneuver is important to minimize the risk of injury to the tail of the pancreas during left hilar dissection. Complete splenic mobilization often requires visualizing the stomach above the spleen. Finally, mobilization of the left colon is complete once the aorta is exposed. Once Gerota's fascia is exposed, the psoas is identified, anterior to which is the ureter. Alternatively, the mid ureter can be found posterior and medial to the gonadal vein. This relationship is particularly important when tracing the ureter to the renal hilum in the case of a right nephrectomy. Care is taken to sweep the gonadal vein medially, separating it from the ureter and avoiding the risk for avulsing it from the vena cava. The ureter is kept intact, which allows it to be used as a handle for anterior and cephalad retraction of the kidney later in the case. At this point the lower pole of the kidney is mobilized within Gerota's fascia. This has the potential for causing significant bleeding in the case of large, lower pole masses or if multiple parasitic vessels are encountered. To help facilitate lower pole mobilization with adequate hemostasis, electrocautery, any of a number of ultrasound-based coagulation devices, or the LigaSure® (Valleylab, Boulder, CO, USA), which uses an electrical current to fuse blood vessels, may be utilized. Prior to the start of dissection, some surgeons recommend placing a small lap pad into the patient. In the event of unexpected bleeding, this can be used to improve visualization, or in the worst case scenario, tamponade bleeding to allow time for open conversion.

With the lower pole of the kidney mobilized, the ureter can be traced cephalad to the renal hilum. Care needs to be taken when dissecting toward the renal hilum in the event of a lower pole accessory vessel that was not visible on preoperative imaging. Retracting anteriorly and cephalad on the kidney allows for better exposure to the renal vein and artery. Judicious use of energy-based dissection may be required to divide the fibrous lymphatic tissue often surrounding the renal artery.

For a left nephrectomy, ensuring the left renal artery is positioned posterior to the exposed renal vein ensures that the superior mesenteric artery is not mistaken for the left renal artery. Next, when the left renal vein is isolated, the gonadal vein can be clipped and divided if necessary. Caution should be exercised at this point to prevent avulsing a potential lumbar vein draining into the posterior surface of the left renal vein.

If the adrenal gland is to be taken, the left adrenal vein can be clipped and divided at this point. Once the renal artery and vein are isolated, an endovascular stapler or clips are used to secure the artery and vein. Once the artery has been divided, if the renal vein does not decompress as expected, thus raising the concern for a renal vein thrombus, or if there is a known renal vein thrombus preoperatively, laparoscopic ultrasound is employed to ensure the thrombus has retracted completely before dividing the vein. After the artery, followed by the vein, has been divided, the decision is made whether to preserve the adrenal gland or to take it with the specimen. For large, central tumors or those located in the upper pole of the kidney, removing the adrenal gland with the kidney should be considered to ensure there are negative margins or if there is any evidence of metastatic or contiguous involvement of the adrenal gland.

In the case of a right nephrectomy, moving superiorly along the IVC will expose the short, right adrenal vein. Care should be taken to avoid avulsing the right adrenal vein, as this can lead to significant hemorrhage. Once divided, the use of energy-based dissection can facilitate expeditious mobilization of the kidney and adrenal gland from the surrounding attachments and renal fossa, while securing potential parasitic vessels feeding the tumor. Care is taken superiorly to avoid inadvertent injury to the diaphragm. At this point, the ureter is clipped and divided, completely freeing the specimen. When taking the left adrenal gland, either the left renal vein can be stapled proximal to the insertion of the adrenal vein, or the adrenal vein can be clipped and divided separately. In the case of an adrenal-sparing nephrectomy, energy-based dissection can be used to effectively dissect and coagulate any small feeding vessels between the kidney and the adrenal gland.

Current evidence does not suggest a benefit to performing a lymph node dissection for T1 or T2 disease in the absence of clinically positive nodes [24, h 31]. However, retrospective data suggest some benefit to improved staging in those with clinically detected nodal disease [25]. Adding to the argument in favor of extended lymphadenectomy, Pantuck et al. demonstrated improved survival in patients with metastatic disease who underwent cytoreductive nephrectomy and lymphadenectomy prior to immunotherapy compared to those who did not receive an extended lymphadenectomy [28].

Depending on the clinical situation and surgeon preference, the lymph node dissection can be performed either laparoscopically or robotically, and is not precluded based on a minimally invasive approach.

Finally, the specimen is entrapped in any commercially available laparoscopic organ retrieval device. The specimen, depending on the size of the tumor, can be removed through a small extension of either the lateral or umbilical trocar incisions, or through a separate Pfannenstiel or midline infra-umbilical incision. A few surgeons have advocated morcellation to minimize the size of the incision necessary for specimen extraction, but the potential for tumor spillage is theoretically higher [32].

## Laparoscopic retroperitoneal radical nephrectomy

### Advantages/disadvantages

The retroperitoneal approach to LRN may be useful in cases of prior abdominal surgeries. However, if the patient is particularly obese or has a large amount of retroperitoneal fat, proper orientation can be difficult. Improper orientation and loss of appropriate landmarks can lead to significant operative challenges and even inadvertent caval transection when mistaken for the renal vein [33]. Furthermore, previous renal surgeries or renal infections can lead to significant perirenal adhesions or scarring, making the retroperitoneal approach even more challenging. Finally, large renal masses with multiple parasitic vessels or those that may involve other organs should not be removed retroperitoneoscopically.

### Positioning

The patient is placed in the full flank position. After the axillary roll and appropriate anterior/posterior bolsters are placed, the table is flexed to extend the space between the 12th rib and the iliac crest. The patient is secured with thick silk or cloth tape to the operative table.

### Procedure

After the patient is prepped and draped sterilely, an incision is made off the tip of the 12th rib large enough to accommodate the surgeon's index finger. With the oblique muscles divided, the lumbodorsal fascia is incised and the retroperitoneum is entered. The surgeon's index finger is inserted into the retroperitoneum, and the psoas muscle and lower pole of the kidney are palpated. A commercially available balloon dilator that accommodates a 10 mm laparoscopic lens is inserted into the incision under direct vision. The potential retroperitoneal space is dissected with the dilating balloon to a volume of approximately 800 ml. After deflating and removing the balloon, a blunt-tipped trocar with a soft collar is placed into the incision. The soft collar on the inside of the incision helps maintain insufflation as well as prevent subcutaneous emphysema. Furthermore, this port does not project far into the working space, therefore not impairing the view of the kidney. The laparoscope is placed through this trocar. Two additional trocars are placed. A 12 mm trocar is placed lateral to the camera port and approximately 2 cm cephalad to the iliac crest. A second 5 mm trocar is placed off the tip of the 11th rib. Finally, an optional additional 5 mm port can be placed off the tip of the 10th rib. When placing the ports medial to the initial camera port, the peritoneal lining must be swept medially or inadvertent peritoneal entry and bowel injury may occur. After the 10 mm 30° lens is placed through the 12 mm inferior port, surgical orientation is achieved based upon the position of the psoas muscle and overlying ureter.

At this point, the psoas muscle and tendon are dissected free of all retroperitoneal fat. Anterior and medial to the tendon will be the ureter. As with the transperitoneal approach, the ureter is traced back to the renal hilum and is used for placing traction on the kidney and hilum. Care is taken at this point as the IVC (for a right nephrectomy) or the aorta (for a left nephrectomy) is medial and in close proximity to the ureter.

For a left nephrectomy, as the ureter is traced to the renal hilum, dissection should be performed bluntly with the suction irrigator in case an ascending lumbar vein is encountered entering the renal vein. If found, the vein is clipped and divided before proceeding to the renal hilum. The ureter is traced superiorly along the medial aspect of the psoas muscle. This helps to keep the dissection in proper orientation and posterior to the kidney. The renal hilum is identified based on pulsation of the renal artery. Gerota's fascia is incised over the pulsation to expose the renal artery and vein. The artery and vein are isolated and divided as described for the transperitoneal approach.

After the kidney has been completely freed from the renal fossa and the ureter divided, the kidney is placed in a laparoscopically deployed organ entrapment device. If the mass and kidney are small, the initial port can be extended in order to deliver the kidney. In cases where the specimen is large, a Pfannenstiel incision is made and the space of Retzius is entered. Matin and Gill described a modified Pfannenstiel incision that is lateralized to the side of the surgery [34]. Dissection is carried down to the anterior rectus fascia and a vertical incision is created along the lateral rectus border. With the fascia and rectus muscle retracted, the transversalis fascia is divided near the pubis and the extraperitoneal space is entered.

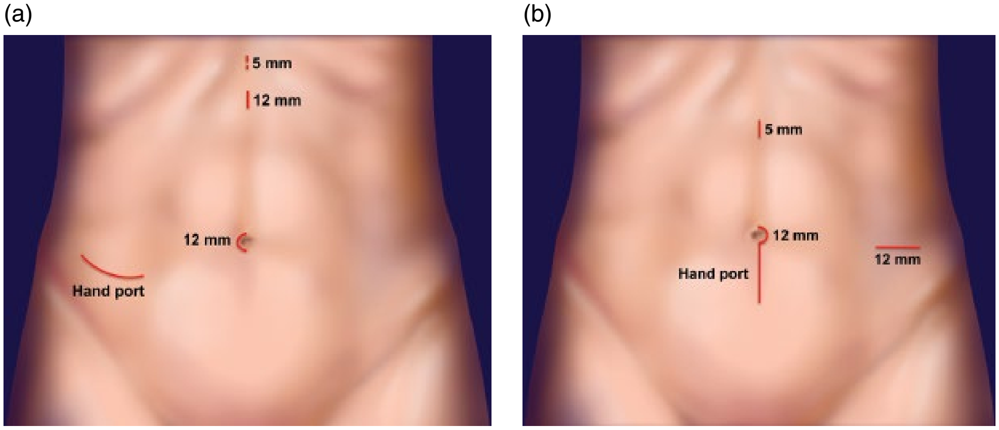

**Figure 92.3** Port placement for a hand-assisted laparoscopic (a) right and (b) left radical nephrectomy. The extra (dotted line) 5 mm port may be utilized for liver retraction. *Source:* Visible Health, Inc., USA. Reproduced with permission of Visible Health, Inc.

Careful blunt dissection into the retroperitoneum through the Pfannenstiel incision can allow for delivery of larger specimens through a lower abdominal incision [34].

See accompanying Video 92.1.

## Hand-assisted laparoscopic nephrectomy

### Advantages/disadvantages

Surgeons with limited experience in pure laparoscopy may find hand-assisted laparoscopic nephrectomy (HALN) advantageous. It is particularly helpful when large renal masses are encountered and significant risk for intraoperative bleeding is anticipated. HALN also allows for the use of tactile sensation, which is useful in cases where the anatomy is obscured. Finally, it may also be used as a technique to convert from a pure laparoscopic approach to open. One disadvantage of this approach, however, is that it often results in a cosmetically suboptimal incision compared to the Pfannenstiel incision when used for specimen extraction. Additionally, maintaining adequate pneumoperitoneum, and thus proper visualization, may be a challenge if the hand port leaks or if the incision for the port is too long.

### Position and trocar placement

Patient position is the same as for the laparoscopic approach. The details of trocar placement and nuances of various hand ports are beyond the scope of this chapter. Briefly, for a right nephrectomy, the hand port is placed in the right lower quadrant, a 12 mm trocar at the umbilicus, another 12 mm camera port in the midline approximately 8 cm cephalad to the umbilicus, and a 3 or 5 mm port immediately inferior to the subxiphoid process for a liver retractor (Figure 92.3a). For a left nephrectomy, the hand port is placed immediately below the umbilicus in the midline, followed by a 12 mm trocar 8–10 cm lateral to and at the level of the umbilicus. Finally, a third 12 mm port is placed 8 cm cephalad to the umbilicus for the camera (Figure 92.3b).

### Procedure

The white line of Toldt is incised sharply while the nondominant hand through the hand port places traction on the colon medially. After the correct plane between the colonic mesentery and Gerota's fascia is entered, the colon is swept medially with the nondominant hand and the suction irrigator. For a right nephrectomy, the renocolic ligament is divided while the nondominant hand retracts the hepatic flexure medially. This exposes the duodenum and Gerota's fascia. As with the pure laparoscopic approach, the duodenum is reflected sharply. At this point, a liver retractor may be placed through the subxiphoid port to elevate the liver and allow better access to the renal hilum. For a left nephrectomy, the splenorenal and splenophrenic ligaments are divided. The hand provides gentle medial traction on the spleen to allow for exposure to the upper pole. The psoas muscle is identified and the ureter and gonadal vessels are isolated. For a right nephrectomy, the ureter is retracted anteriorly with the hand while the gonadal vessels are swept medially with the suction irrigator. On the left, the vessels are taken with the ureter. The ureter is then traced toward the renal hilum.

At this point, the lower pole of the kidney is mobilized and retracted anteriorly and cephalad with the hand, while the renal vessels are dissected free with a combination of blunt and energy-based dissection. In cases where a large renal mass partially obscures the renal hilum, it may help for the surgeon to use an index finger to palpate the renal artery. After sufficient exposure of the vein and artery is achieved, the endovascular stapler or clips are used to divide the renal artery, followed by the vein, while maintaining exposure of the renal hilum with the surgeon's hand. At this point, the decision must be made whether to keep the adrenal or remove it with the kidney. On the right side, if the adrenal gland is to be taken with the kidney, the nondominant hand is used to retract the kidney laterally while the suction irrigator is used to bluntly dissect the adrenal vein. After the short adrenal vein is exposed, it can be clipped and divided sharply. Once divided, a combination of energy-based dissection and finger-fracturing of the surrounding renal attachments expeditiously mobilizes the kidney and adrenal gland. While doing this, the surgeon is also simultaneously palpating and securing parasitic vessels feeding the tumor.

Finally, the ureter is ligated and divided, completely freeing the specimen. If the decision is made to preserve the adrenal gland, dissection of the adrenal is performed by retraction on the adrenal with the off-hand and division of the adrenal gland from the kidney with energy-based dissection.

The remaining portion of the nephrectomy is completed as described above. We recommend the use of a laparoscopically deployed entrapment device for HALN. This helps protect the exposed incision from the unnecessary risk of tumor spillage/implantation.

## Robot-assisted laparoscopic radical nephrectomy

### Advantages/disadvantages

RLRN allows urologic surgeons with minimal laparoscopic skills to more easily transition open surgical techniques into a minimally invasive procedure. In addition, some surgeons prefer the use of robotic assistance in cases where hilar and/or retroperitoneal lymph node dissection is indicated. Disadvantages of this procedure include the lack of a haptic interface and the increased operating room costs imposed when using the robotic approach. Furthermore, operative time may be increased as a result of docking and undocking the robot [35]. The following will describe the use of the da Vinci robotic system (Intuitive Surgical, Inc., Sunnyvale, CA, USA) for a radical nephrectomy.

### Positioning

Robotic renal surgery can be performed both transperitoneally and retroperitoneally. For a transperitoneal approach, the robot is docked from the back of the patient at a 20° angle toward the head of the patient (Figure 92.4a). When performing retroperitoneal robotic renal surgery, the robot is docked directly over the head of the patient (Figure 92.4b). The patient is positioned in

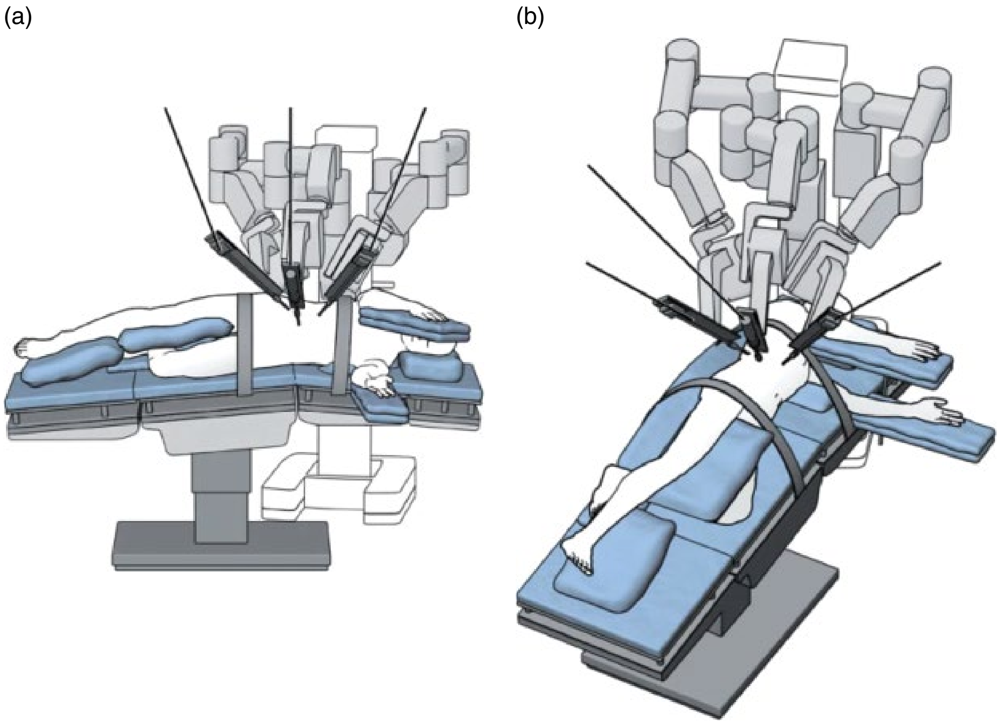

**Figure 92.4** Robot docking position for (a) transperitoneal and (b) retroperitoneal laparoscopic radical nephrectomy.

the modified lateral decubitus position as previously described for the transperitoneal approach with attention paid to the arm ipsilateral to the affected kidney. This arm should be positioned medial and cephalad, as it could limit the movement of the subcostal robotic instrument.

### Procedure

With the patient properly positioned, pneumoperitoneum is achieved to a pressure of 15–20 mmHg, as described above. A 12 mm umbilical trocar is placed and the abdominal contents are inspected for adhesions and to rule out bowel injury after establishment of pneumoperitoneum. Two additional 8 mm robotic trocars are placed, each 8 cm from the umbilical trocar and from each other. A 12 mm assistant trocar is placed approximately 8 cm inferior to the umbilical trocar. An additional 5 mm assistant trocar is placed superior to the umbilical port if needed for organ retraction. When using the standard system, the trocars need to be spaced out further to avoid robotic arm collisions. When using the da Vinci Xi robotic series, the slimmer profile of the robot allows the trocars to be placed in closer proximity to each other. Using the robotic Maryland forceps or fenestrated bipolar and electrocautery shears, the white line of Toldt is identified and incised sharply while the assistant is retracting medially on the bowel.

Once the proper plane between the mesocolon and Gerota's fascia is established, much of the bowel mobilization can be done bluntly. After adequate bowel mobilization, the ureter and gonadal vessels are exposed and lifted anteriorly to expose the psoas muscle. The assistant may retract anteriorly on the ureter, allowing the robotic surgeon to use both hands for additional dissection. An additional port for the robotic fourth arm could be placed and utilized for retraction.

For a right nephrectomy, the gonadal vessel needs to be swept medially in order to prevent inadvertent injury to or avulsion of the gonadal vein. Blunt dissection using both robotic arms for traction–countertraction sweeping movements is performed when progressing cephalad along the psoas toward the hilum. For a left nephrectomy, the spleen is mobilized as described for the pure laparoscopic approach. In the case of a right nephrectomy, the Kocher maneuver is performed exclusively with sharp dissection in the same manner as previously described. With the lateral attachments of the kidney left in place, exposure of the hilum and renal vasculature is performed. The Maryland dissector or the fourth arm (with a Prograsp installed) is used to retract the kidney laterally to place mild traction on the hilum for dissection. The bedside assistant may also be utilized for this. Electrocautery is often required to divide the dense lymphatic and fibrous tissue surrounding the renal artery. For large renal masses on the right, the robot may be helpful in dissecting an obscured renal artery from an interaortocaval approach. After the renal vasculature has been sufficiently exposed, the assistant inserts an endovascular stapler to divide the renal artery, followed by the renal vein. Alternatively, the assistant can ligate the vessels with clips. In addition, the robotic system allows the console surgeon to apply locking clips if the bedside assistant is unable to.

With the renal vasculature divided, an adrenal-sparing nephrectomy may be performed as indicated. After the kidney has been fully mobilized medially, it is freed from the surrounding renal fossa and lateral attachments. At this point, liberal use of electrocautery and bipolar energy through the Maryland forceps or fenestrated bipolar can help minimize bleeding from parasitic vessels. Finally, with the kidney completely free within the abdomen, the pneumoperitoneum is slowly dropped and the renal fossa observed for several minutes to inspect for bleeding. The robot is undocked and the specimen is removed through an extraction site that was marked previously on the patient.

## Results

Since the original description of laparoscopic nephrectomy in 1991, the minimally invasive approach to radical nephrectomy has gained wide acceptance throughout the urologic community and is now considered the treatment of choice for isolated renal masses not amenable to nephron-sparing surgery [32].

Compared to open surgery, laparoscopy has been shown to result in less postoperative pain, less analgesic requirement, early postoperative ambulation, faster return of bowel function, shorter hospital admissions, improved cosmesis, and overall decreased convalescence period [23, 36–40]. As urologic surgeons adopted LRN, multiple series published in the literature have reported oncologic outcomes comparable to those for open radical nephrectomy (Table 92.1). The longest current series runs over 11 years postoperatively. The overall, cancer-specific, and recurrence-free survival rates at 10 years in this group were 65%, 92%, and 86%, respectively. From this series, 71% of renal masses were T1, 15% were T2, and 10% were T3a [41]. Several series have also demonstrated equivalent oncologic outcomes when comparing HALN to the open approach. Though these studies were limited by their retrospective nature, their results are nonetheless compelling [39, 42, 43]. Although RLRN should have similar outcomes to LRN, there are limited follow-up data available.

**Table 92.1** Outcomes of hand-assisted laparoscopic (HALN), robotic-assisted laparoscopic (RALRN), pure laparoscopic (Lap), and open nephrectomies.

| Study | Cohort size | Surgical approach | Follow-up duration[a] | Recurrence-free survival (%) | Cancer-specific survival (%) |
|---|---|---|---|---|---|

## Conclusions

Significant advances have been made in the field of minimally invasive surgery for kidney cancer, leading to improvements in patient convalescence, while providing comparable or equivalent oncological outcomes for renal malignancies. With the development of robotic technology and incorporation into formal training programs, these advances can be adopted easily by those with limited laparoscopic skills, thus extending the reach of minimally invasive surgery to a greater number of patients.

# Robotic Partial Nephrectomy: Advancements and Innovations

*Sameer Chopra, Mehar Bains, & Inderbir S. Gill*

*USC Institute of Urology, Keck School of Medicine, University of South California, Los Angeles, CA, USA*

## Introduction

Despite recent debate about whether partial nephrectomy (PN) confers any overall survival advantage over radical nephrectomy in patients with small renal masses [1, 2], the relevance and importance of nephron-sparing surgery remains unquestioned [3–7]. Minimally invasive techniques such as robotic PN provide oncologic and functional outcomes equivalent to those from open PN while decreasing patient morbidity [7], and have increased the utilization of PN surgery in the field.

Post-PN kidney function depends primarily on the volume and condition of the remnant renal parenchyma, and secondarily upon the duration of ischemic insult during PN [8]. To minimize renal damage during PN surgery, warm ischemia time is best restricted to less than 20–25 minutes [8, 9]. During PN surgery, the amount of kidney excised strongly correlates with the ischemia time required to achieve that excision and reconstruction. Almost always, the deeper, larger, and more complex a particular renal tumor, the longer the ischemia time required to excise that specific tumor and perform the necessary renal reconstruction; conversely, the smaller and simpler the renal tumor, the shorter the ischemia time needed to perform that particular PN. Thus, the volume of kidney excised/preserved during PN is inextricably interlinked with the ischemia duration. Recent surgical innovations seek to maximize PN outcomes by optimizing surgically modifiable factors, such as minimizing/eliminating global ischemia, performing tumor excision with a thin negative margin, meticulous point-specific parenchymal hemostasis, careful renorrhaphy, all to secure maximal preservation of vascularized, functional, normal kidney parenchyma [10]. Minimally invasive technique aside, the initial surgical innovations for reducing warm ischemic injury during PN were "early-unclamping" techniques, which then evolved to selective arterial clamping aimed at achieving only tumor-specific ischemia [11] and now zero-ischemia, unclamped techniques in an attempt to maximally retain global kidney function. While minimizing ischemia during the PN, surgical techniques such as sculpted tumor excision, with pinpoint suturing to achieve hemostasis, further minimize functional parenchymal loss [12].

In this chapter, advancements of robotic PN technique are described. These technical nuances minimize global renal ischemia, maximize normal kidney parenchyma preservation, and perform meticulous sutured renal reconstruction with minimal blood loss and complications. We also discuss imaging modalities that assist in the propagation of these techniques.

## Preoperative preparation

### Preoperative evaluation

Preoperative evaluation for PN consists of a detailed history and physical examination, baseline laboratory values such as serum creatinine and estimated glomerular filtration rate, which is calculated using the modification of diet in renal disease formula. A three-dimensional renal-dedicated computed tomography (CT) or magnetic resonance imaging (MRI) scan using 0.5–2 mm slice thickness provides details about tumor location, depth, proximity to the collecting system, and renal contact surface area. Arterial and venous phases of the CT scan provide detailed depiction of the extrarenal hilar vascular anatomy.

During the initial clinical visit, the patient is counseled as to all treatment alternatives, including active surveillance with percutaneous renal mass biopsy [13] and various interventive surgical options. Risks, benefits, potential complications, and the possibility of conversion to open surgery or radical nephrectomy are discussed prior to obtaining surgical consent.

Antiplatelet and anticoagulant medications are discontinued or bridged prior to surgery, as clinically indicated. Medical and anesthesia clearance is obtained. No routine formal bowel preparation is performed prior to surgery. However, per surgeon's preference, a clear liquid diet can begin the prior evening to surgery, with/without bisacodyl suppository or an oral saline cathartic, such as magnesium citrate or sodium phosphates. Antibiotics, such as cefazolin, are administered intravenously preoperatively. To prevent deep venous thrombosis, pneumatic compressive stockings and 5000 U subcutaneous heparin are administered 2 hours prior to the procedure and continued 8–12 hourly postoperatively. Anticoagulation is continued for up to one month after discharge, per surgeon discretion. Upon commencement of the robotic procedure, 1.52 liters of crystalloid intravenous fluids are administered to expand the intravascular volume and initiate a brisk diuresis.

## Operative room setup

We use a four-arm technique for robotic PN; use of the fourth robotic arm provides fixed traction during key maneuvers, enhanced exposure for hilum and tumor dissection, retraction of overlying perirenal fatty tissue for further exposure, less dependence on the assistant, and increased diversity of surgical maneuvers. The bedside assistant is positioned facing the patient's abdomen, and the scrub technician is positioned behind the assistant. Video monitors are placed at the head and foot end of the patient on the side of the robot for easy viewing by the surgical team. A Mayo stand is placed next to the assistant where frequently used instruments are placed. The da Vinci® Surgical System (Intuitive Surgical Inc., Sunnyvale, CA, USA) is docked posterior to the patient with the camera arm coming in to the patient at an angle of 15° in line with the camera trocar site (described in detail below) (Figure 93.1).

## Patient positioning

Under general endotracheal anesthesia, the patient is placed in a modified (60–70°) lateral decubitus position, with the umbilicus over a mid break in the table. An axillary roll is placed, the table is flexed as necessary (usually minimally compared with open flank surgery), and copious padding is used and positioned to support the buttocks and flank. Pillow(s) are placed between the flexed lower and straight upper leg. The upper arm rests on a well-padded arm board (or pillows) without tension on the brachial plexus. Tape is used to secure the patient around the hips, shoulders, and thighs to ensure stability when rolling the table to facilitate bowel retraction (Figure 93.2a). Care is taken to adequately pad all pressure points and place all limbs in neutral position to minimize positioning injuries. The abdominal skin is shaved with clippers and the patient is prepped and draped in standard sterile fashion for a transperitoneal robotic surgery. An 18 Fr urethral catheter is inserted and an orogastric tube is placed. A standard time-out is called prior to incision.

## Instrumentation and equipment list

### Equipment

- Da Vinci® Si or Xi Surgical System (Intuitive Surgical Inc.)
- 0° and 30° robotic scope (Intuitive Surgical Inc.)
- Mono-polar scissors (Intuitive Surgical Inc.)
- ProGrasp™ forceps (Intuitive Surgical Inc.)
- Bipolar Grasper™ forceps (Intuitive Surgical Inc.)
- Needle drivers (Intuitive Surgical Inc.)
- Clip appliers (Intuitive Surgical Inc.).

### Trocars

- 12 mm visual obturator trocar (Visiport, Medtronic Parkway, Minneapolis, MN, USA)
- 5 mm trocar × 2
- 8 mm trocars × 2
- Bariatric 8 mm trocars × 2.

### Assistant instruments

- Suction irrigator device (bariatric length)
- Laparoscopic spoon forceps
- 5 mm locking atraumatic grasper
- Hem-o-lok® applier – bariatric (Teleflex Medical, Research Triangle Park, NC, USA)
- Medium (purple) Hem-o-lok clips (Teleflex Medical)
- Laparoscopic needle driver
- Laparoscopic scissor
- 15 mm specimen entrapment bag
- Laparoscopic Doppler ultrasound probe
- Surgicel® hemostatic gauze (Ethicon, Johnson & Johnson, New Brunswick, NJ, USA)
- FloSeal hemostatic matrix and laparoscopic applier with obturator (bariatric length) (Baxter International, Deerfield, IL, USA)
- Laparoscopic bulldog clamps

## Step-by-step technique: robotic partial nephrectomy

### Step 1: Pneumoperitoneum and trocar placement (Figure 93.2b–c)

For the vast majority of tumors, we prefer a transperitoneal approach. Our trocar placement configuration allows for treatment of all renal tumors irrespective of location, whether upper pole, lower pole, or hilar. Four robotic trocars are employed with 1–2 assistant ports. Veress needle pneumoperitoneum is established at 13–15 mmHg and the first trocar (12 mm for the Si robot; 8 mm for the Xi) is inserted on the same level of the 12th rib just lateral to the pararectus line. The robotic camera is then inserted and the peritoneal cavity inspected to

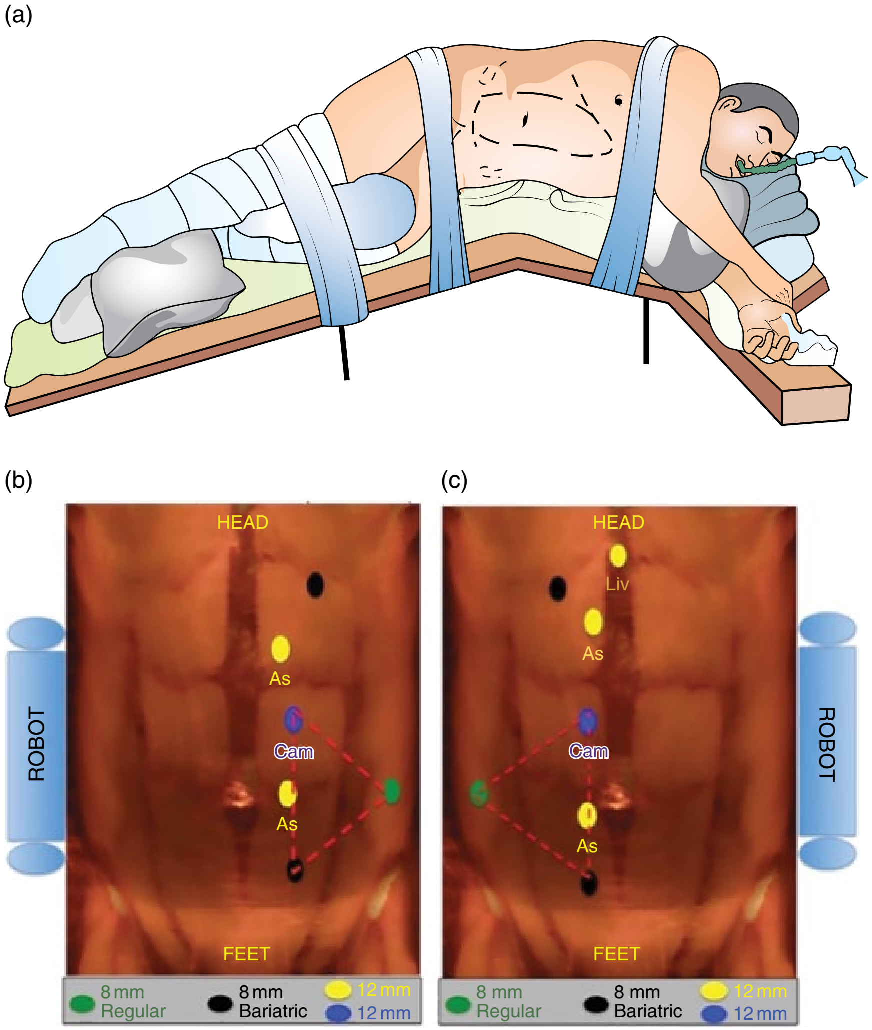

**Figure 93.2** Patient positioning and port placement. (a) Patient positioning. (b) Port placement for a left partial nephrectomy. (c) Port placement for a right partial nephrectomy.

ensure no organ damage occurred during entry. The bariatric 8 mm trocar is located at the costal margin slightly cepahald and lateral to the pubic bone (just lateral to the medial umbilical ligament). A traditional 8 mm trocar is placed two fingerbreadths above the anterior superior iliac spine. Assistant trocars are placed in their traditional locations: one trocar between the camera trocar and uppermost robotic arm, another between the camera and the lower robotic arm. Both assistant trocars are placed slightly more medial than the other trocars.

The trocar configuration should form an equilateral triangle between the camera port, the lower bariatric port, and the lateral traditional robotic port to reduce instrument clashing. For a right robotic PN, an additional incision is made at the xiphisternum for the liver retractor. In this trocar configuration, the lower bariatric trocar is the most "active" arm, regardless of laterality. The use of a bariatric, and thus longer, trocar enhances the reach of the robotic instruments when treating upper pole tumors. Specimen retrieval typically occurs in the more caudal assistant port, though this is patient dependent. The surgical table is tilted, and the da Vinci is docked posterior to the patient with the camera arm coming in to the patient at an angle of 15° in line with the camera port. Robotic instruments are inserted into the peritoneal cavity under direct vision.

## Steps 2–3: Bowel mobilization and hilum dissection

These are standard procedural steps for robotic PN and have been discussed elsewhere. Briefly, the Gerota's fascia-covered kidney and the ureterogonadal packet are visualized and retracted laterally. The main renal artery and vein are circumferentially mobilized and each is encircled with minivessel loops.

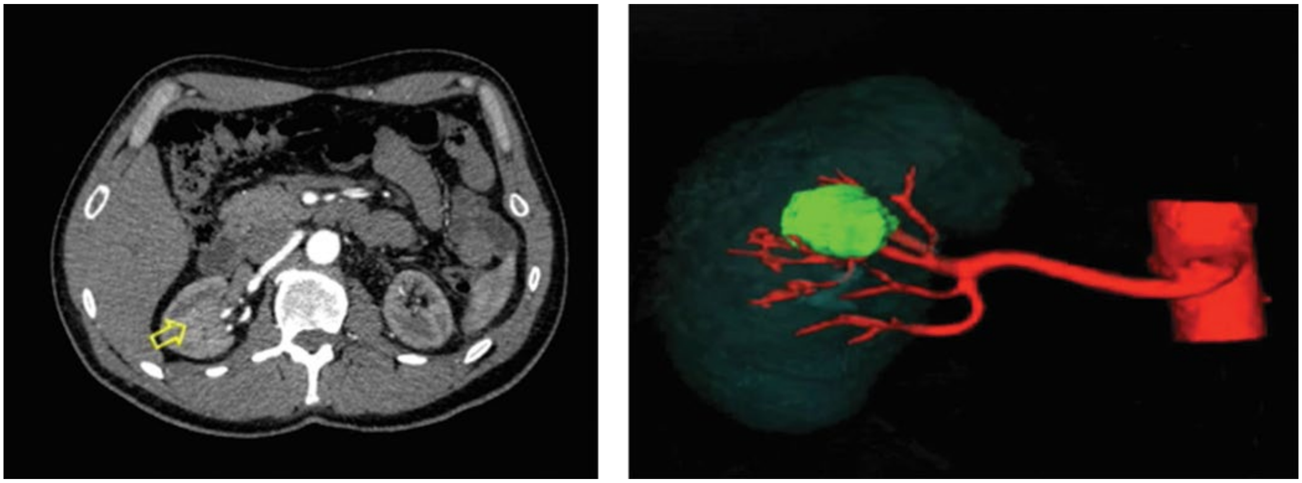

**Figure 93.3** CT and 3D remodeling of kidney with vasculature and tumor reconstruction. This is done to allow the surgeon to gain a complete understanding of the relevant renal arterial branches to help guide and orient the surgeon during arterial microdissection.

## Steps 4–5: Hilar microdissection and superselective arterial clamping

### Medially located tumors and visible confirmation of interrupted perfusion

Radiologic images from the preoperative CT are carefully examined, with or without 3D reconstruction, to gain a complete understanding of the relevant renal arterial branches to help guide and orient the surgeon during arterial microdissection (Figure 93.3). The main renal artery and vein remain unclamped during this procedure. Meticulous and selective vascular microdissection of only the arterial branches (tertiary, quaternary) that supply the tumor is performed toward the tumor and into the renal sinus in a medial-to-lateral direction. Microdissection of the tertiary renal arterial branches is advanced by dissecting into the renal sinus and developing the peripelvic plane of Gil-Vernet [14].

A radial nephrotomy incision is created on the concave, hilar edge of the kidney directly overlying the arterial branch that supplies the tumor (Figure 93.4). Vessel loops are used to isolate and atraumatically retract arterial branches to allow advancement of the microdissection as it approaches the tumor. As the dissection is advanced intrarenally, the radial nephrectomy incision can be extended an additional 2–3 cm if necessary. The radial nephrotomy incision should be made on the hilar edge of the kidney that overlays the anterior surface of that specific arterial branch. Once the terminal, tumor-supplying vessel is identified, a neurosurgical aneurysm microbulldog is placed temporarily (Figure 93.5a). This is done to confirm selective devascularization of the tumor, which is confirmed by visual inspection (normal color and turgor), “fire-fly” indigo-cyanine green fluorescence, and, only if necessary, color Doppler ultrasound (Figure 93.5b). Ongoing perfusion of the surrounding normal kidney is also confirmed. Topical papavarine can be applied onto the renal hilar vessels to counteract any vasospasm.

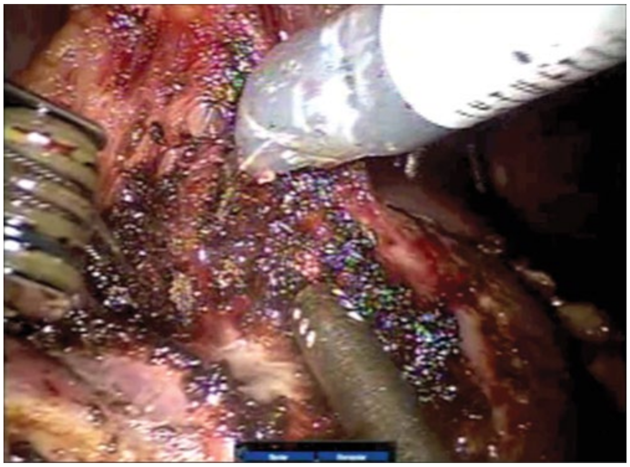

**Figure 93.4** Radial nephrotomy. A radial nephrotomy is made to increase exposure of the tumor and its vasculature, in order to facilitate superselective arterial clamping.

### Laterally located and intrarenal tumors

We recommend clamping of the main renal artery during PN for lateral or intrarenal tumors. This is because the arterial supply of these tumors is multidirectional, which therefore does not lend itself to selective clamping.

## Steps 6–8: Tumor scoring, excision, and renorrhaphy

These steps are detailed elsewhere in this book. Specific steps include circumferential scoring of the tumor and

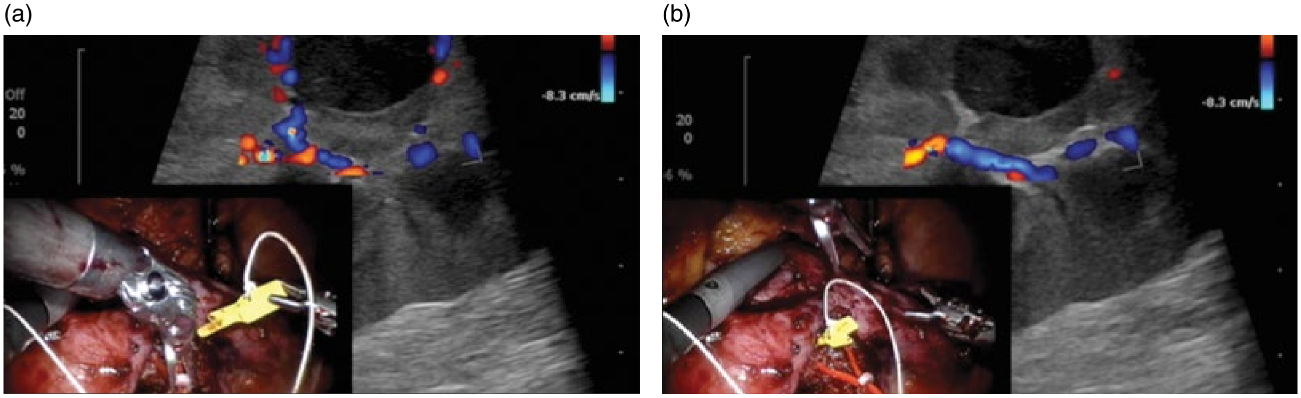

**Figure 93.5** Superselective clamping to facilitate partial nephrectomy. (a) Drop-in color Doppler ultrasound is used to observe the blood supply to the tumor prior to superselective clamping. (b) Following application of the microbulldog, color Doppler ultrasound is again used to demonstrate the observed arterial perfusion to the tumor and all non-tumor-bearing kidney.

tumor excision using both electrocautery and cold scissors. The tumor is bluntly and sharply dissected off the underlying intrarenal vessels, preserving intact the larger intrarenal and hilar vessels. Hemostasis is achieved in the partial nephrectomy bed using a combination of Hem-o-lok clips and point-specific parenchymal suturing. Hem-o-lok clips are applied to the vessels directly supplying the tumor in the deep resection bed; these are then under-sown to prevent clip migration into the calyceal system. The collecting system is suture-repaired with a running 3-0 polyglactin on SH-1 needle. Sutured renorrhaphy of the partial nephrectomy bed is performed, typically without the use of a bolster; however, a bolster can certainly be used to maximize parenchymal hemostasis, per surgeon preference. Water-tightness of the repair is confirmed by repeat retrograde injection of dilute methylene blue through the indwelling ureteral catheter. A biologic hemostatic agent is layered onto the partial nephrectomy bed.

### Step 9: Completely unclamped (zero-ischemia), “minimal-margin” partial nephrectomy

This technique has now evolved into our preferred approach, and is a technical advancement to our prior, superselective segmental arterial clamping technique described above. With this approach, all vascular clamping is completely eliminated; there is no requirement for vascular microdissection or use of microbulldog clamps. In addition, tumor excision is performed with a minimal-margin (1–2 mm) adjacent to the capsular edge. This technique is based on the following anatomic considerations: (i) intrarenal architecture, both parenchymal and vascular, is radially oriented; (ii) the vast majority of small clinical T1 renal tumors possess a distinct intrarenal pseudocapsule; (iii) the tumor–parenchyma interface is histologically altered with sclerotic changes; and (iv) the intrarenal arteries at this junctional interface immediately adjacent to the tumor edge are typically smaller in diameter and fewer in number. These facts form the reasoning for performing a sculpted enucleo-excision in the plane immediately adjacent to the tumor capsule – the “minimal-margin” plane. The purpose of this technique is to maintain a uniform, 1 mm section of benign parenchymal tissue on the tumor capsular surface, without denuding the capsule, which occurs during traditional tumor enucleation.

The renal parenchyma is scored approximately 2 mm from the tumor edge under ultrasound guidance using electrocautery. With the fourth robotic arm, the perirenal fat directly overlying the tumor is retracted, thus elevating the tumor from the kidney. A radial nephrotomy incision is deepened along the cephalad and caudal edges of the tumor, each about 2–3 mm in length. This is done along the scored margin with electrocautery at a setting of 100 W. This bloodless incision is further developed by placing the tip of the robotic bipolar forceps in the left robotic arm into the nephrotomy incision and gently and deliberately opening its jaws (Figure 93.6). This opens the parenchyma along the naturally existing radial plane adjacent to the tumor with cold dissection; point electrocautery is used only sparingly to coagulate any small intrarenal vessels and to guide the enucleative plane. The capsular incision is developed circumferentially around the tumor and then deepened with blunt dissection; the robotic forceps is used to retract the tumor away, off the partial nephrectomy bed. It is important to note that the renal parenchyma is bluntly separated and not incised during the excision. This allows for the dissection to be kept along the natural, relatively avascular intrarenal plane, minimizing injury to the interlobar vessels. If there are any larger intrarenal

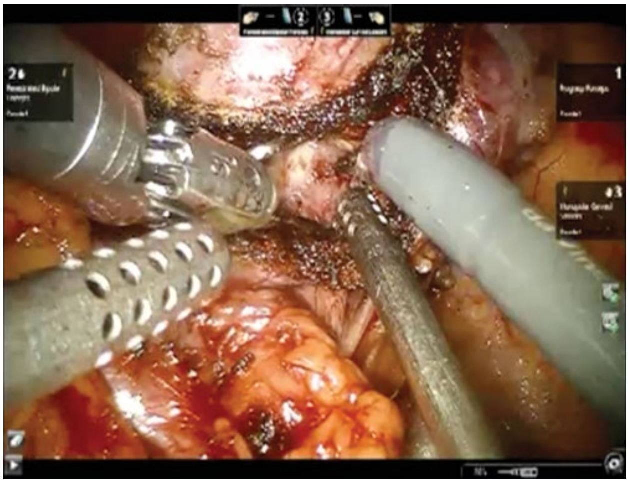

**Figure 93.6** "Minimal-margin" partial nephrectomy. The bloodless incision is further developed by placing the tip of the robotic bipolar forceps in the left robotic arm into the nephrotomy incision and gently opening its jaws. This opens the parenchyma along the naturally existing radial plane adjacent to the tumor with cold dissection; point electrocautery is used only sparingly to coagulate any small intrarenal vessels and to guide the enucleative plane.

vessels feeding the tumor, these can be specifically dissected and controlled with a Hem-o-lok clip before transection. During this procedure, two suction apparatuses are required, one for parenchymal compression and one for suction and irrigation. The assistant at bedside uses the suction cannula to compress any bleeding vessels transiently, while point-specific suturing is performed to secure hemostasis. Once completed, the calyceal system is repaired in a water-tight manner using 3-0 polyglactin on an SH-1 needle.

### Step 10: Near infrared fluorescence using indocyanine green

Similar to the use of Doppler ultrasound to help facilitate superselective PN, intravenous indocyanine green dye is used to confirm tumor devascularization. It can also be used simultaneously to confirm ongoing global perfusion of the remaining normal kidney, providing visual confirmation that the clamping of the terminal artery does not compromise vascularity of the nontumor, normal kidney (Figure 93.7).

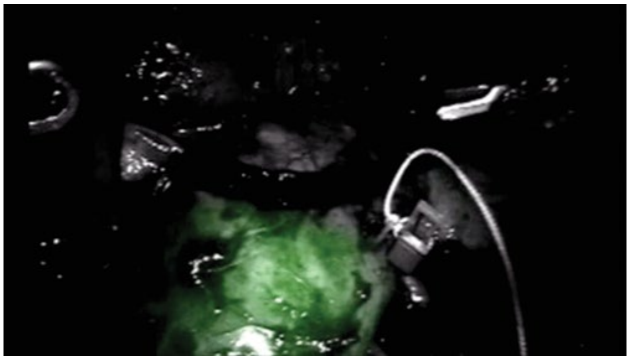

**Figure 93.7** Intravenous indocyanine green dye is used to confirm tumor devascularization and ongoing global perfusion to the remaining normal kidney parenchyma.

## Postoperative management

Following the procedure, the patient is restricted to a clear liquid diet initially and advanced as tolerated. On postoperative day 1, parenteral antibiotics are discontinued and ambulation is encouraged throughout the hospital stay. The Jackson–Pratt (JP) drain is removed once the JP output has decreased to <50 ml per day. Creatinine analysis of the JP fluid drainage determines if there is a urinary leak. Out-of-town patients from longer distances are required to stay in a nearby hotel for 3–4 days to ensure smooth recovery before returning home. Postoperative follow-up depends upon individual patient histology.

## Special considerations

Complications associated with PN surgery include positive cancer margins; compromise of renal function; and urological complications (urine leak, bleed). These and other common complications have been described elsewhere.

## Follow-up

Follow-up comprises the standard procedural steps for robotic PN, which have been discussed elsewhere. See Video 93.1.

# Intraoperative Assessment of Tumor Resection Margins

*Ilan Z. Kafka & Timothy D. Averch*

*Department of Urology, University of Pittsburgh Medical Center, Pittsburgh, PA, USA*

Every year there are an estimated 338 000 new diagnoses of renal cell carcinoma (RCC) and over 140 000 deaths from it in North America, Europe, and Australia [1]. With this high incidence rate of newly diagnosed RCC and consequent descending stage migration, the use of nephron-sparing surgery (NSS), whenever technically feasible, has significantly increased in comparison to radical nephrectomy during the last decade [2, 3].

A generally suggested indication for NSS is a small renal mass, usually 4 cm or less, located peripherally and easily amenable to resection [4]. However, emerging data suggest that NSS can be performed in patients with anatomically amenable tumors larger than 4 cm, provided that an adequate surgical margin can be safely obtained [5]. As for radical nephrectomy specimens, positive surgical margins (PSMs) are not common, with reported rates of up to 6% [6]. If encountered, the recommendation is to mark with ink the doubtful area of the specimen. If the margins are positive, their anatomic location and whether there is extension into adjacent structures should be described. If there is renal vein invasion, the status of the cut edge of the renal vein or the vena cava should be indicated as well. However, high-powered, prospective, randomized studies to identify the predictors of PSMs after radical nephrectomies are still lacking.

Although oncologic outcomes have been demonstrated to be comparable between procedures (radical nephrectomy vs. NSS), a common concern is the violation of tumor during resection, leaving residual disease in the resection bed [7]. One of the fundamental rules of nephron-sparing oncologic renal surgery is that the largest amount of healthy renal tissue possible should be preserved without compromising the oncological outcomes. Conventionally, concerns about local recurrence due to inadequate tumor excision and the risk of pseudocapsule invasion on the parenchymal side has led most surgeons to remove normal-appearing parenchyma around the tumor. More recently, large series have reported the results of simple enucleation of renal masses versus traditional partial nephrectomies, showing functional and oncological results equivalent to standard partial nephrectomy [8–10].

It has been suggested that a tumor-free margin in the pathologic specimen, regardless of its size, can be sufficient to achieve complete local excision after NSS [11]. However, in some cases, NSS can result in incomplete cancer removal and consequent PSMs. Although NSS has been suggested not to be associated with an increased risk of local recurrence or metastatic disease [12–16], a recent multi-institutional study, which retrospectively evaluated 1240 patients undergoing NSS and analyzed the relationship between positive margins and risk of relapse, concluded that a PSM in NSS increases risk of disease recurrence, primarily in patients with adverse pathologic features (e.g. pT2–pT3a or Fuhrman grade III–IV) [17].

In a recent large prospective multi-institutional study, Schiavina et al. aimed to evaluate predictors of PSM after NSS for renal cell carcinoma. Eight hundred consecutive patients were evaluated and 761 and 39 patients achieved negative and positive margins, respectively. Patients with PSMs were significantly older compared with those with negative margins. A higher incidence of PSMs was observed when NSS was performed for renal masses located in the upper pole. A lower rate of PSMs was found in patients treated with simple enucleation rather than standard partial nephrectomy. A greater incidence of PSMs was found in Fuhrman 3/4 tumors [18].

In another recent study, Khalifeh et al. [19] looked at 943 robotically assisted NSS cases. PSM cases showed statistically significant higher local recurrence and metastasis rates when compared to the negative margin counterparts.

During NSS, intraoperative frozen section of the nephrectomy bed is commonly performed to confirm the presence of a negative surgical margin [20]. In 2007 a multi-institutional survey in the United States and Europe showed that intraoperative frozen sections in NSS were performed at 15 of 17 (88.2%) of the institutions and random biopsies of the tumor bed were routinely performed at 5 (29.4%). A more recent survey showed that 69% of urologists reported only sometimes obtaining a frozen section during NSS [21].

Despite being highly specific, the sensitivity of tumor bed frozen section in NSS in predicting the presence of a PSM in the resected tumor has been shown to be only 30% [22]. This low sensitivity is secondary to discrepancies between intraoperative frozen section pathology and final pathology and could be explained by numerous factors, including technical reasons, such as missing the remaining tumor during random biopsy, limited availability of special stains, freezing and drying artifacts, and/or pathologist error. Contributing to the controversy is the question whether a positive surgical margin is actually reflective of residual tumor in the patient. Some evidence suggests that even with a positive surgical margin, the remaining tumor burden can be destroyed by use of cautery on the resection bed [23].

Alternatives to intraoperative frozen section have also been developed and studied. Intraoperative imprint cytology examinations have been successfully used in other tumor entities to assess surgical margins. One of the main advantages of imprint cytology is its ability to assess the entire tumor surface rather than a specific area and it has been proven time- and cost-effective [24]. A study by Palermo et al. analyzed 82 patients who underwent either open or minimally invasive NSS with imprint cytology and frozen section evaluation. The results were compared with permanent histology as the gold standard. They found that imprint cytology revealed a PSM in 10 tumors (12%). The sensitivity of the cytologic examination was 87.5%, positive predictive value (PPV) 70%, specificity 95.9%, and negative predictive value (NPV) 98.6% [24]. In another comparative study, imprint cytology showed a specificity of 98%, sensitivity of 100%, a PPV of 90%, and NPV of 100%, while frozen section showed a specificity of 99% and sensitivity of 98% in assessing surgical margins with a PPV of 95% and NPV 98%. They concluded that imprint cytology examinations exhibit equivalent diagnostic value compared with frozen section analysis, while being low-cost and quicker [24, 25].

Intraoperative ultrasound has also been used to guide resection and for margin assessment in NSS. Doerfler et al. performed intraoperative ultrasonography localization before and after tumor removal during laparoscopic NSS, and they found the ultrasound analysis of surgical margins to be negative in all except one patient. The final histologic examination of all specimens confirmed ultrasound results with a 100% correlation [26]. Surgical specimen (*ex vivo*) ultrasound of the surgical specimen's pseudocapsule has been reported to be feasible and efficient at determining the accuracy of margin status. Another work published by Doerfler et al. showed that intraoperative *ex vivo* ultrasound in NSS determined margin status with 100% sensitivity and 97% specificity. Its PPV and NPV were 50% and 100%, respectively [27]. Veeratterapillay et al. showed there is a positive correlation between margin on extracorporeal specimen ultrasound and pathological margins [28].

In an attempt to eliminate frozen section tumor base biopsy and its related time delay, Yilmaz et al. performed "gross intraoperative evaluation (GIE)" in which they evaluated surgical margins of open NSS specimens macroscopically by intraoperative examination of the tumors divided *ex vivo* into two halves. They concluded that GIE of resected NSS specimen has high sensitivity and safety for the evaluation of surgical margins [29].

Indocyanine green (ICG) is the most commonly used contrast agent for intraoperative imaging, as it absorbs and emits light in the near infrared portion of the electromagnetic spectrum (about 800–2500 nm). When injected intravenously, ICG binds to albumin and lipoproteins, remaining predominantly intravascular until excreted by the hepatobiliary system. It is used to enhance intraoperative decision-making in evaluating vasculature, tumor margin identification, and lymph node dissemination of malignancy. Various systems have been developed that can be used in conjunction with open, laparoscopic, and robotic-assisted surgery. Tobis et al. [30] demonstrated the use of intravenous ICG with simultaneous near infrared fluorescence (NIRF) imaging at the time of open partial nephrectomy. Renal tumors were well demarcated by ICG and highly hypofluorescent when compared with the surrounding normal parenchyma. In a study by Manny et al. [31] the degree of hypofluorescence could not be reliably used to differentiate malignant versus benign tumors in 100 consecutive patients undergoing robotic partial nephrectomy with NIRF guidance. In their study, they found NIRF imaging to have a PPV of 87%, NPV of 53%, sensitivity of 84%, and specificity of 57%. This poor differentiation between normal and malignant tissue has been suggested to be related to a nonstandardized dosing of ICG [32].

Optical coherence tomography (OCT) is one of a number of emerging optical biopsy techniques that provide high-resolution, real-time, cross-sectional imaging of tissues. Similar to B mode ultrasound, OCT relies on information gathered by reflected energy. In comparison, however, OCT utilizes near-infrared light rather than acoustic waves and does not require direct contact with tissue as does ultrasound. OCT been investigated for renal imaging in evaluating kidney morphology and renal masses. Preliminary studies have investigated OCT's ability to distinguish benign from malignant renal tumors. Barwari et al. [33] concluded that *ex vivo* OCT attenuation coefficients were different between normal renal parenchyma and RCC tissue, RCC tissue showing a significantly higher attenuation coefficient than normal parenchyma.

Studies are being conducted to assess OCT *in vivo* and, if successful it may be applied to evaluate surgical margins after partial nephrectomy or combined with biopsy needles to provide a functional optical biopsy in which cross-sectional images can be correlated with histopathology [34].

Although there is no clear agreement in the clinical evidence, local recurrence seems to be more likely in patients with PSMs, especially in those with high-grade tumors. Improvement of metastases and cancer-specific survival, as observed in midterm follow-up studies, seems to be comparable to that in patients with negative surgical margins. Considering the worldwide low risk of local recurrence, development of metastasis, or cancer-specific mortality, careful surveillance could be the best management option for most patients with PSMs after NSS. The value of intraoperative tumor resection bed analysis in guiding the patient's intraoperative management remains to be defined. However, it is still recommended to take site-directed biopsies of the partial nephrectomy specimen bed if there is suspicion of an incomplete resection during the procedure or after gross inspection of the specimen (see Video 94.1).

# Laparoscopic Radical Nephroureterectomy

*Wayland J. Wu & Jessica E. Kreshover*

*The Arthur Smith Institute for Urology, Zucker School of Medicine at Hofstra/Northwell, Lake Success, NY, USA*

## Introduction

Laparoscopic approaches to renal surgery have gained popularity as a result of decreased morbidity for patients and equivalent oncologic outcomes. Since it was first described in 1991, laparoscopic nephroureterectomy (LNU) has also gained popularity [1]. This surgery presents a new set of difficulties over renal procedures, with the surgical field spanning the hemi-abdomen down into the ipsilateral pelvis. Arguably, the approach to resection of the distal ureter is the most difficult part of this case and certainly is highly variable and surgeon dependent. With the laparoscopic approach to nephrectomy described in Chapter 92, this chapter focuses on the means of managing the distal ureter for completion of a nephroureterectomy. There is no approach that has been shown to be clearly superior to another in either oncological or perioperative outcomes and so surgeon preference remains the mainstay of the decision for management of the distal ureter.

## Indications

LNU is used for patients with upper tract urothelial tumors, which accounts for about 5% of all urothelial tumors [2]. The surgery involves the removal of the kidney and the entirety of the ureter, including the ureteral orifice with a cuff of bladder urothelium. This remains the gold standard approach for management of renal pelvis and ureteral tumors. With many tumors being lower grade and stage and with increasing goals to maintain renal function, less invasive means can be used, including endoscopic management (ureteroscopic and percutaneous) and segmental ureterectomy [3–5]. Nephroureterectomy with *en bloc* excision of the ureteral orifice with bladder cuff, however, remains the optimal choice for bulky, high-grade, and/or invasive tumors.

Open nephroureterectomy (ONU) uses two incisions and with this comes significant morbidity. LNU decreases this morbidity at a minimum for the nephrectomy portion of the procedure. The indications for laparoscopic approach remain the same as those for open. The principles of oncologic control should apply regardless of approach – open versus laparoscopic. There are copious data comparing laparoscopic and open approaches.

### Oncological outcomes

A large multicentered retrospective study out of France found no difference in 5-year cancer-specific survival between laparoscopic and open nephroureterectomy [6]. In addition to their main outcome, there was also no difference in 5-year recurrence-free survival, metastasis-free survival, or complications between surgical techniques, including when stratified by pathological stage. Despite suffering from inherent flaws with retrospective study design, this study offered a highly powered comparison between surgical approaches.

Similar findings were obtained by Fairey et al. in their multi-institutional study [7]. They had a total of 849 patients, approximately half in the laparoscopic cohort, who had a median follow-up of 2.2 years without significant differences in disease-specific survival between laparoscopic and open groups. Multivariate analysis did not find that surgical approach influenced survival, but the authors did express some concern as there was a slight trend towards worse recurrence-free survival in the laparoscopic group (hazard ratio = 1.01, $P = 0.08$). Again, limitations exist because the study is retrospective.

Companion website: www.wiley.com/go/smith/textbookofendourology

A prospective study by Simone examined 80 patients randomized to LNU or ONU [8]. Subjects who underwent a laparoscopic approach had lower average blood loss and length of stay but 5-year cancer-specific survival and metastasis-free survival were also lower; however, this difference was not statistically significant. When stratified by tumor stage, subjects with stage pT3 had statistically significant lower cancer-specific survival and metastasis-free survival, suggesting laparoscopic may be inferior to open approach in patients with locally advanced disease. Despite having a small sample size owing to the relative rarity of upper tract urothelial carcinoma, the data provided are supportive of LNU as being an oncologically sound operation at least of low-stage disease.

### Perioperative outcomes

Given the size of the surgical field spanning the hemiabdomen, there is significant morbidity associated with an open approach, predominantly with two sizeable incisions. Hospital length of stay may serve as a surrogate marker of patient convalescence after surgery. A retrospective analysis of a major British national registry found minimally invasive (pure or robot-assisted laparoscopic) nephroureterectomy afforded a significantly decreased hospital stay compared to open (5 vs. 8 days) [9]. The superiority of minimally invasive nephroureterectomy in reducing length of stay is echoed in several other studies [6, 8, 10].

The American College of Surgeons National Surgical Quality Improvement Program (NSQIP) is a multi-institutional database providing perioperative outcomes of various operations. Hanske et al. queried this database and compared outcomes between patients who underwent open or minimally invasive nephroureterectomy [11]. They found no statistically significant difference in 30-day postoperative complications, readmission rate, and perioperative mortality. Minimally invasive approach was superior to open with regard to transfusion rate (9.2% vs. 21.5%, $P < 0.05$) and need for repeat surgical intervention (odds ratio = 0.24 95% confidence interval (CI) 0.07–0.83, $P < 0.05$).

Although all these series seem to indicate comparable oncologic and perioperative outcomes, there remain multiple approaches for excision of the distal ureter during a laparoscopic approach.

## Operative technique

### Patient positioning

Patient positioning is similar to that for laparoscopic nephrectomy as described in Chapter 92 with modified lateral decubitus positioning. The hips should be more externally rotated to open the pelvis and expose the lower quadrant. It is often advantageous to mark the midline prior to positioning to aid in appropriate trocar and incision alignment before the skin shifts when the patient is positioned on their side. This positioning allows for access for nephrectomy as well as the distal ureterectomy portion for purely laparoscopic and for open excision approaches. This also prevents patient repositioning.

There are various ways to manage the distal ureter. The entire ureter, including the intramural portion, ureteral orifice, and bladder cuff, should be removed. Approach used is generally based on surgeon preference. There are minor variations among techniques for distal ureteral management but most fall into four main categories: purely laparoscopic, open, endoscopic “pluck,” and endoscopic “intussusception.” The endoscopic approaches require patient repositioning into the dorsal lithotomy position for that portion of the case. The modified lateral decubitus positioning is still used for the nephrectomy portion.

### Procedure

#### Pure laparoscopy

For a purely laparoscopic approach, trocars should be placed to allow for dissection in the hemi-abdomen as well as the pelvis (Figure 95.1). Just as in renal surgery, trocars are shifted laterally in obese patients. Upper abdominal trocars are placed and used just as that described for a nephrectomy (umbilical camera port and upper midline and lateral ports for right and left hands). A laparoscopic nephrectomy takes place (as described in Chapter 92) without transection of the ureter. Clips should be placed across the ureter as early as possible below the level of the primary tumor to prevent tumor spillage. Once the kidney is freed, the ureter is traced down into the pelvis. It is about at the level of the iliac

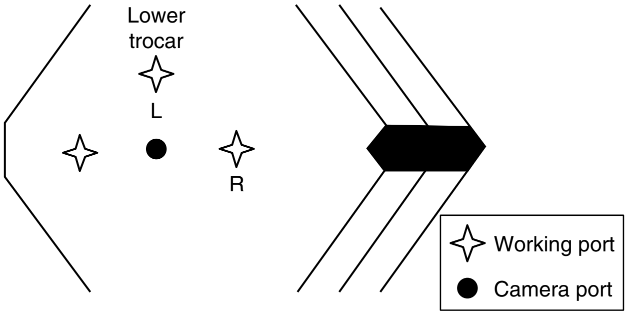

**Figure 95.1** Trocar layout for purely laparoscopic right nephroureterectomy. Initial trocars used for nephrectomy portion of the case are designated. L and R represents which hand is used for each port. Orientation of picture: left – caudad; right – cranial; top – right flank; bottom – left flank.

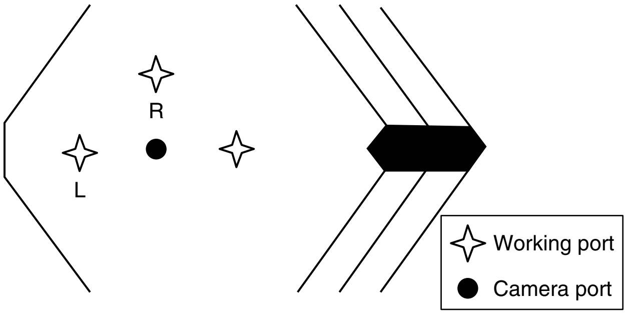

**Figure 95.2** Trocar layout for purely laparoscopic right nephroureterectomy. Trocars used for distal ureterectomy portion of the case are designated. L and R represents which hand is used for each port. Orientation of picture: left – caudad; right – cranial; top – right flank; bottom – left flank.

vessels where a lower abdominal approach must be taken. It is at this point that the trocar configuration is transitioned into the pelvis (Figure 95.2). The camera port remains at the umbilicus and right and left hands are shifted to the trocars within the pelvis (lateral and lower midline trocars). The surgical bed can be adjusted into a Trendelenburg position to help in visualization by shifting the colon cephalad.

Dissection takes place along the ureter distally. The peritoneum should be incised medial to the obliterated (medial umbilical ligament) to enter the perivesical space lateral to the bladder. Great care should be taken to identify and transect the ipsilateral superior vesical vasculature to prevent bleeding. The round ligament/vas deferens can be clipped and divided. Traction can be placed on the ureter to aid in dissection down to and through the intramural portion. There are two primary means of managing the ureter at this point – laparoscopic stapling or laparoscopic excision with bladder cuff.

Use of a laparoscopic stapling device for distal ureteral transection risks incomplete resection of the ureteral orifice if dissection is not taken distally enough. Additionally, if staples are exposed within the bladder urothelium, this can be a nidus for stones.

For laparoscopic excision of the ureter, an extravesical or transvesical approach can be used. In an extravesical approach, the intramural ureter is dissected circumferentially until the bladder is entered. It is often advantageous to place a stay suture lateral to the ureteral orifice to prevent tumor spillage and aid in visualization of the cystotomy and prevention of bladder retraction prior to closure. Extravesical closure then takes place. Care should also be taken to prevent deep suture placement that could compromise the contralateral orifice. For a transvesical approach, the anterior bladder is incised and the ureteral orifice is visualized directly. The ureteral orifice and bladder cuff can be visualized directly and incised circumferentially. A combination of extra- and transvesical dissection can then be used to free the ureter completely. The site of ureterectomy should be closed followed by the cystotomy.

The specimen can then be delivered through a low midline incision (incorporating the lower midline abdominal trocar site and possibly umbilical site).

### Open excision

As extraction of the specimen is needed *en bloc*, many surgeons argue for use of open excision of the distal ureter and bladder cuff. This approach most mimics the open approach. The patient is positioned as previously described in the purely laparoscopic approach section. The nephrectomy portion is performed and ureteral dissection is taken down as distally as possible. With this modified positioning, the bed can be externally rotated slightly to more closely mirror supine positioning (and thus prevent repositioning of the patient). A Gibson incision is performed in the ipsilateral pelvis. Pfannenstiel and low midline incisions may also be used (Figure 95.3). The same ureteral dissection takes place with incision of the peritoneum medial to the medial umbilical ligament and the ureter can be traced down to the bladder. Options for distal excision again include extravescial or transvesical approaches. A transvesical approach with an anterior cystotomy is most common as again it most closely mimics the *en bloc* resection that takes place via an open approach. It also ensures complete excision of the ureteral orifice with a bladder cuff. The final *en bloc* specimen can be removed via this incision. Complete extravesical excision can also be used, requiring closure of only that single bladder cystotomy.

### Endoscopic "pluck"

Endoscopic techniques were created to try to obviate the need for an open excision and ease distal dissection of the ureter. The endoscopic portion of this case takes

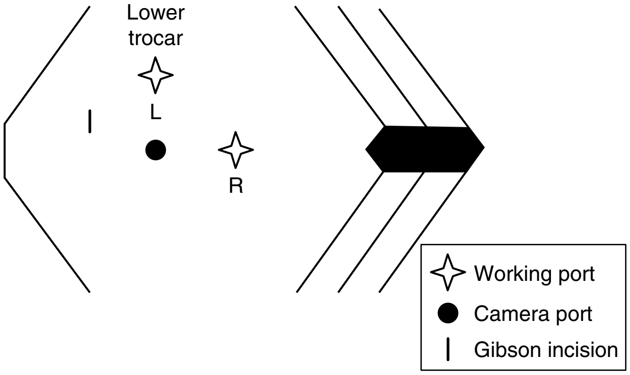

**Figure 95.3** Surgical incisions/trocars for right nephroureterectomy with open distal ureterectomy. Gibson incision is designated. L and R represents which hand is used for each trocar port. Orientation of picture: left – caudad; right – cranial; top – right flank; bottom – left flank.

place first and with the patient in a dorsal lithotomy position. A resectoscope can be used to resect the ureteral orifice along the path of the intramural ureter down into the perivesical fat. Another option is use of a Collins knife to circumscribe the ureteral orifice with a bladder cuff and then dissect the intramural ureter down into the perivesical fat [12]. Once complete, the patient is positioned in the modified lateral decubitus position and a "pure laparoscopic" approach is undertaken (see above). With the endoscopic dissection having previously taken place, it is easier to place tension on the ureter intra-abdominally and thus free the ureter from the bladder muscle. An extravesical closure then takes place and the entire specimen can be extracted via a midline incision.

With this technique it is important to try to place clips on the ureter as early as possible once the intra-abdominal portion of the case begins. There have been many procedures proposed to accomplish ureteral occlusion prior to the intra-abdominal portion. The pluck technique has higher risk of tumor spillage and hence is most appropriate for patients with proximal/renal pelvis tumors that are low grade [13]. This technique is not appropriate for patients with very distal ureteral tumors or concomitant bladder tumor due to risk of tumor spillage and seeding.

#### Endoscopic "intussusception"

An alternative method involves transurethral removal of the distal ureter by removing the kidney and ureter piecemeal with the distal portion removed by intussuscepting the ureter into the bladder. This is also known as the "stripping" technique. An endoscopic approach is used initially with the patient in the dorsal lithotomy position. A bulb-tipped ureteral catheter is placed into the ipsilateral ureter first with the bulb occluding the ureter. This potentially can be done in the lateral decubitus position with the pelvis and perineum prepped into the surgical field. A laparoscopic nephrectomy is then performed after the patient is repositioned into the modified lateral decubitus position. The ureter is dissected free and the bulb is identified within the ureteral lumen. The ureter is tied off above and below the bulb to secure the ureter to the catheter. The ureter is clipped proximal to this and then the ureter is transected. The renal unit and proximal ureter are extracted via a midline incision. The patient is then repositioned into the lithotomy position. Traction is placed onto the ureteral catheter to intussuscept the ureter into the bladder and a bladder cuff is made transurethrally using a Collins knife until the ureter is freed (similar to the pluck technique). The specimen is removed per urethra [14].

## Results

The superiority of a technique should be judged by its ability to remain oncologically sound while minimizing operative morbidity. Distal ureterectomy during nephroureterectomy is a critical step to prevent tumor recurrence. The goal is to excise the diseased urothelial tissue down to and including the ureteral orifice. The intramural ureter should be removed with negative margins. In addition, caution should be taken when removing the ureter from the bladder to prevent spillage into the retroperitoneum.

Distal ureterectomy via laparoscopic stapling (or using a sealing device) efficiently ligates the diseased collecting system to prevent tumor spillage and avoids creating a cystotomy. A retrospective single-center experience by Hattori et al. examined distal ureteral management via open, pure laparoscopic (with distal ureteral stapling or sealing) approach and combined approach (LNU with open distal ureteral excision) [15]. When examining the laparoscopic groups, 53 patients underwent pure laparoscopy compared to 36 who had a combined approach. They found the pure laparoscopy group required less time to dissect the distal ureter ($0.8 \pm 0.5$ hours vs. $1.8 \pm 1.1$ hours) but no difference in time to convalescence, blood loss, or overall operative time. The ureteral orifice was not excised in 15% of patients in the pure group versus 11% of patients in the combined group (authors did not indicate if this difference was statistically significant). Recurrence rates were 25% in each group and all of these were treated successfully by transurethral resection. With regard to oncologic outcomes, there was no statistically significant difference in cause-specific survival, extravescial recurrence, and intravesical recurrence between open, pure laparoscopy, and combined cohorts.

In a small (36 patients) retrospective study by Ritch et al., open excision of the distal ureter and bladder cuff was compared to the laparoscopic techniques of pure laparoscopic dissection and closure and laparoscopy with extravesical stapling [16]. With respect to perioperative outcomes, the laparoscopic approaches had significantly shorter operative time and the laparoscopic dissection and closure had significantly shorter (two days) length of stay than the other two groups (perhaps because of smaller sample size). With respect to oncologic outcomes, there was no statistically significant difference in 2-year recurrence-free survival between the groups. It is important, however, to note that in the laparoscopic stapling group, 50% of patients had cystoscopic evidence of an ipsilateral ureteral orifice remnant.

Kapoor and colleagues retrospectively compared three techniques and their effects on tumor recurrence following radical nephroureterectomy. Their series included 820 patients who underwent ONU or LNU and had their distal ureter excised either via an open intravesical, open extravesical, or an endoscopic pluck technique with either resection down to the perivesical fat or circumferential excision with occlusion of the distal ureteral orifice with an EndoLoop® (Ethicon, Inc., Somerville, NJ, USA) [17]. More than half of all patients (53.4%) underwent laparoscopic nephroureterectomy and among these, the distal ureter was approached via open extravesical (46%), intravesical (34%), and endoscopic pluck (22%) techniques. Their group found the intravesical technique to have the best recurrence-free survival rate for both overall tumor recurrence and intravesical recurrence at 2 and 5 years. With a median follow-up of 24.6 months, their long-term results should be interpreted cautiously.

A larger series of both open and laparoscopic cases by Xylinas et al. was presented by combining data from 24 institutions comprising 2681 patients. They retrospectively reviewed patients who underwent open intravesical, open extravesical, or endoscopic pluck approaches to the distal ureter (for both laparoscopic and open nephroureterectomy). For the endoscopic pluck approach, the ipsilateral ureteral orifice was fulgurated with a resectoscope and a 1 cm margin was incised around the intramural ureter. The dissection was carried down to the perivesical fat [18]. In this series, the vast majority of patients underwent ONU (80.9%) with open intravesical excision being the most common method of managing the distal ureter (67.5%). Endoscopic approach was the least common method (3.2%), but the endoscopic technique was most utilized in patients who had undergone a laparoscopic approach (84.7%). Recurrence-free survival was 71%, 73%, and 77% for intravesical, extravesical, and endoscopic approaches to distal ureterectomy at 2 years, respectively. At 5 years, the rates were 66%, 66%, and 69% for intravesical, extravesical, and endoscopic methods, respectively. There were no statistically significant differences between the three groups when compared pairwise. With regard to intravesical tumor recurrence, the highest recurrence rate was seen in the endoscopic management group, with recurrence-free survival of 42% at 5 years versus 58% for open intravesical excision and 51% for open extravesical excision. Endoscopic management and concomitant carcinoma-in-situ were independent predictors of tumor recurrence in a matched-pair analysis with patients matched for TNM stage and nodal status. Cancer-specific survival and overall survival were similar across all management groups however.

There is copious literature that speaks to the efficacy of the laparoscopic approach to nephroureterectomy. The management of the distal ureter within this literature is highly variable, however. Most LNU data comprise of open resection technique for management of the distal ureter which obviously most closely resembles a pure open approach. As such, it is not surprising that the oncological outcomes for open and laparoscopic approaches are not significantly different. The data on endoscopic techniques are more limited and generally altered by inherent selection bias, with patients having lower grade and lower stage tumors. Both endoscopic techniques (pluck and intussusception) risk tumor spillage and require repositioning of the patient intraoperatively. There are far fewer data on a pure laparoscopic approach. What does seem clear is that laparoscopic extravesical stapling techniques have a high rate of incomplete resection of the ureteral orifice, which violates one of the primary oncologic principles. More data are needed to ensure that a pure laparoscopic approach with distal ureteral excision and bladder closure is oncologically comparable to its open counterpart.

## Introduction

Bladder cancer is largely a disease of the elderly, presenting with a median age of 73 years in men and 74 years in women [1]. It is the fourth most common cancer in the United States; in 2016, an estimated 76 960 new diagnoses and 16 390 deaths were predicted [2]. Bladder cancer is also the fourth leading cause of cancer death in men aged 80 and older [2]. In managing patients with bladder cancer, the primary therapy relies on initial staging from transurethral resection of bladder tumor (TURBT) [1]. For patients with muscle-invasive bladder cancer and for those with high-risk recurrent non-muscle-invasive disease, open radical cystectomy (ORC) remains the gold standard of treatment [1]. Attempts at a minimally invasive approach were first made in the early 1990s with the introduction of laparoscopic cystectomy [3, 4], followed by the introduction of robot-assisted radical cystectomy in 2003 [5]. When compared to ORC, recent studies have shown laparoscopic radical cystectomy (LRC) to be a safe, feasible, and reliable alternative with lower morbidity and perioperative complications [6–10]. Furthermore, robot-assisted radical cystectomy (RARC) has also been shown to be a safe alternative, presenting with reduced perioperative complications, less estimated blood loss with lower need for perioperative blood transfusion, hastened gastrointestinal recovery, lower narcotic requirement, and shorter length of stay [11–19]. Given the technical similarities between LRC and RARC, both approaches will be addressed collectively; however, given its growth in popularity, a greater focus will be placed on robotic cystectomy.

## Indications and patient selection

LRC and RARC are usually indicated for patients with organ-confined, nonbulky bladder cancer [20] with the goal of surgical cure of disease. On rare occasions, palliative cystectomy is performed in patients with severe symptoms from disease as an adjunct to chemotherapy. Contraindications to robot-assisted cystectomy generally vary from patient to patient and should be assessed on a case-by-case basis with decisions to proceed based on the surgeon's experience. For example, patients with prior abdominal surgery can present with extensive intra-abdominal adhesions [21] requiring careful lysis of adhesions. Yet, while patients with previous abdominal surgery have a higher risk of postoperative complications, the likelihood of a safe completion of robot-assisted cystectomy is not affected [21]. Similarly, although previous pelvic radiation is a relative contraindication to a robotic approach, in experienced hands complications rates after RARC do not show significant differences between patients with or without a history of pelvic irradiation [22]. Other relative contraindications include evidence of locally advanced disease and obesity [20].

## Operative technique

### Patient preparation

Prior to surgery, bowel preparation includes 48 hours clear liquid diet, 300 ml of magnesium citrate, and one tablespoon of mineral oil the day before surgery. If the patient is undergoing continent cutaneous diversion

with the right colon, 4 liters of polyethylene glycol is used for bowel prep the day before surgery, and antibiotics (1 g of oral neomycin and 1 g of erythromycin), with one tablespoon of mineral oil are given the day before surgery. Rectal enema is also done the evening before and morning of surgery.

## Operative setup

Specifics of the operative setup for RARC will be dictated by the characteristics of the individual surgeon's operating room. At our institution, we employ a single assistant on the patient's right side, and feel that at least three monitors are needed to allow for each team member to have optimum viewing. Figure 96.1 provides a schematic overhead view of our preferred operative setup.

## Patient positioning and preparation

As illustrated in Figure 96.2, the patient is placed in a dorsal lithotomy position using standard operative stirrups. The arms are tucked and protected using egg-crate foam padding, legs placed in sequential compression stocking devices, and a cross-shoulder harness is used to secure the patient to the operating table. The table is tilted to a steep 30–40° Trendelenburg position. A urethral catheter is placed sterilely on the operative field. Along with perioperative antibiotics, we routinely administer 5000 units of subcutaneous heparin prior to the start of the operation.

## Trocar configuration

Initial insufflation of the abdomen is done via the Veress needle technique to 15 mmHg. Figure 96.3 outlines our standard trocar configuration for RARC. A camera trocar is placed in the periumbilical location using a 10–12 mm, blunt, disposable trocar. At 10 cm lateral and 4 cm inferior to the camera trocar, a left 8 mm robotic trocar is placed. Three centimeters superior to the anterior superior iliac spine (ASIS), a second 8 mm robotic trocar is placed along the midaxillary line. At 4 cm inferior and 10 cm lateral to the camera trocar, a right 8 mm is placed. The main right assistant trocar is placed at 3 cm superior to the ASIS in the midaxillary line using a Versaport™ Plus 5–15 mm trocar (Covidien/Medtronic, Minneapolis, MN, USA). Midway between the right robotic trocar and the camera trocar, a 5 mm AirSeal® Access Port (Conmed, Utica, NY, USA) is placed, which is used primarily for suction–irrigation.

## Steps of the procedure

The techniques described below apply directly to robotic cystectomy; laparoscopic cystectomy, however, follows a similar procedural flow with noted differences in the instruments used. We begin the procedure with identifying and dissecting the right ureter by incising the posterior peritoneum along the white line of Toldt and sweeping the bowel medially to expose the psoas muscle. The ureter can usually be readily identified medially along the psoas at its crossing of the external iliac artery. Proximal dissection is performed first to approximately the level of the gonadal vessels, with care taken to preserve blood supply and to avoid direct grasping. Distal dissection is then performed to the level of the ureteral hiatus, with the final distal dissection performed after the division of the anterior pedicle.

Development of the avascular plane between the left bladder and pelvic sidewall reveals the anterior bladder pedicle, which contains the superior vesicle artery. The pedicle can be isolated and transected by various techniques, including the robotic vessel sealer. Once the pedicle is divided, the dissection of the remainder of distal ureter is performed. Prior to transection of the ureter, a large clip is applied distally and a second large clip with a long suture attached is applied proximally, which will facilitate identification duration the later steps of the procedure. Once the clips are secured, the ureter is transected sharply. A similar dissection is carried out on the right side, exposing the right anterior bladder pedicle, ureter, and pelvic sidewall.

After both the anterior pedicle and ureter are divided, a posterior plane is developed by separating the bladder from the rectum. The surgeon lifts the bladder anterior while the bedside assistant retracts the posterior peritoneal edge. Using a combination of blunt and sharp dissection, the posterior plane between the bladder and rectum beneath the posterior leaflet of Denonvilliers' fascia is carried as distally as possible to the level of the prostatic apex, allowing for identification of the posterior pedicles of the bladder. The posterior bladder pedicles are divided using the vessel sealer device for non-nerve-sparing operation, and large Hem-o-lok® (Teleflex Medical, Research Triangle Park, NC, USA) clips in a nerve-sparing procedure. The division is complete once the endopelvic fascia is encountered.

The endopelvic fascia is then divided sharply as caudally as possible, because once the bladder is released from the anterior abdominal wall, the posterior prostatic apex becomes difficult to visualize. The prostatic pedicles are then divided using either the vessel sealer device or Hem-o-lok and titanium clips depending on desired nerve-sparing. During this dissection, to avoid injury to the rectum, the bladder and prostate are retracted superomedially while the rectum is retracted posteriorly using the robotic third arm and prograsp, respectively.

The bladder is released from its anterior abdominal attachment by removing the urachus with the bladder en bloc and taking wide peritoneal wings. The puboprostatic ligaments, which are seen after entering the space of Retzius, are preserved for orthotopic urinary diversion. In nonorthotopic diversion, the urethra is not preserved and the puboprostatic ligaments are divided. The dorsal vein complex (DVC) is secured using a 0-polyglactin suture. Once secured, the DVC is divided, exposing the underlying urethra. In nerve-sparing procedures and in patients undergoing orthotopic neobladder, we avoid the use of electrocautery during this dissection and during the division of the uretha. The anterior portion of the uretha is then divided to expose the urethal catheter. The catheter tip is then pulled through the urethral opening, and after the lumen is secured using a large clip to prevent possible tumor spillage, the catheter is divided using scissors. The remainder of the urethra and the remaining apical attachments are divided, and a 15 mm Endo Catch™ bag (Covidien/Medtronic, Minneapolis, MN, USA) is used to immediately collect and remove the bladder, prostate, and seminal vesicles.

Regardless of surgical approach, pelvic lymphadenectomy (PLND) is a central component of radical cystectomy, and the extent of lymphadenectomy has been correlated with improved oncologic outcomes [23–27]. Although various factors can influence lymph node yields, including method of lymph node submission and variability in pathologic practices and reporting, several studies have demonstrated that experienced surgeons can perform a PLND using robot-assisted surgery comparable to that performed using an open technique [28–30]. Timing of the lymph node dissection is generally dependent on surgeon preference. We begin our PLND after the entire extirpative portion of the procedure is finished by completely skeletonizing the external iliac iliac vessels and removing its surrounding lymphatic tissue. Liberal application of clips are used during lymphadenectomy to minimize the risk of postoperative lymphocele. The borders of our PLND are Cooper's ligament inferiorly, the genitofemoral nerve laterally, and the sacral promontory medially, up to the level of the aortic bifurcation. All presacral, hypogastric, external iliac, obturator, and common iliac lymph node packets are removed en bloc. After ipsilateral dissection, packets are immediately placed in a 10 mm Endo Catch retrieval device, and contralateral dissection is then performed. Nodal packets are placed in separate bags and can be distinguished by placing a knot or clip on one of the retrieval bags.

Prior to the urinary diversion, the left ureter is transposed to the right side of the pelvis through a window created posterior to the sigmoid mesentery and superior to the aortic bifurcation just anterior to the great vessels. The assistant places a grasper underneath the sigmoid colon and the tie on the left ureter is placed in the grasper and delivered to the right side of the patient.

Before the robot is undocked, we place a 15 Fr round Jackson–Pratt drain through the left 8 mm robotic trocar. For orthotopic neobladders, the drain is placed after the vesicourethral anastamosis has been completed robotically.

After the robot has been undocked, the periumbilical cameral incision is extended inferiorly in a curvilinear fashion around the umbilicus. Depending on the body habitus of the patient, the incision used for specimen extraction and extracorporeal urinary diversion typically ranges from 5 to 7 cm. The three separate Endo Catch retrieval bags are removed through this incision, although in female patients the specimens can be removed through the vagina. Urinary diversions including ileal conduit, continent cutaneous diversion, and orthotopic ileal neobladder and the bilateral ureteral anastomoses are performed in the standard open fashion [31, 32].

For patients undergoing orthotopic neobladder, the newly created neobladder is brought down into the pelvis. We then place a urethral catheter per urethra and into the opening created in the neobladder and the catheter balloon is inflated with 15 ml of sterile water and the catheter placed on mild traction to bring the neobladder in closer proximity to the urethra. Prior to redocking of the robot for the urethral–neobladder anastomosis, a suprapubic tube and ureteral stents, brought through a single stab wound in the right lower quadrant, are used to stabilize the neobladder and facilitate the urethral–neobladder anastomosis. The robot is then redocked, pneumoperitoneum is re-established, and the urethral–neobladder anastomosis is performed as shown in Figure 96.4. All wounds are copiously irrigated with sterile water and subsequently closed in a running subcuticular fashion.

## Special considerations for female cystectomy

In female patients, radical cystectomy typically involves concomitant hysterectomy, bilateral salpingo-oophorectomy, and resection of the anterior vaginal wall. However, in select patients (i.e. anterior bladder tumors) preservation of the internal genital organs may be considered, which can provide good functional outcomes, improve sexual function, and preserve potential for fertility [33].

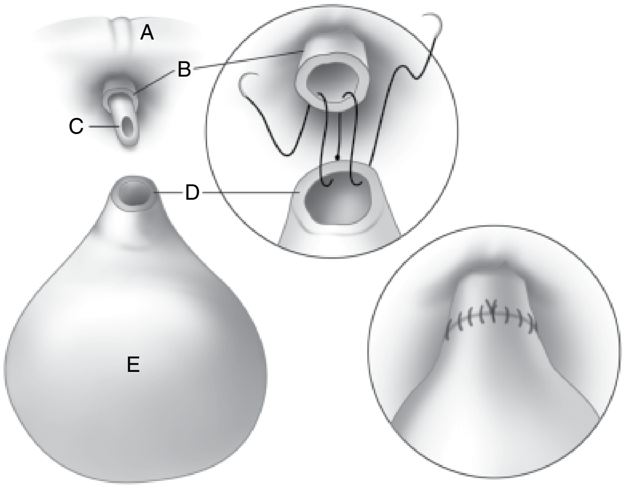

**Figure 96.4** Running urethral–neobladder anastomosis displaying (A) pubic bone, (B) urethra, (C) urethral catheter, (D) everted mucosa of neobladder neck, (E) neobladder. *Source:* Golombos DM. *Robot-Assisted and Partial Cystectomy*, 2017. Berlin: Springer-Verlag. Reproduced with permission of Springer.

When performing a radical cystectomy in a female patient, a sponge stick is placed in the vagina at the beginning of the case. The labia majora can be sutured together to prevent loss of pneumoperitoneum through the vagina, although this is rarely necessary. After ureteral mobilization as previously described, the uterine and ovarian vessels are identified and divided using either Hem-o-lok clips or the vessel sealer device, followed by identification and transection of the round and cardinal ligaments. The uterus, fallopian tubes, and ovaries may be sutured to the bilateral umbilical ligaments to facilitate the posterior dissection. The peritoneum is incised in the rectouterine pouch, and with the aid of the sponge stick, the fundus is opened at the posterior fornix below the level of the insertion of the cervix. The dissection proceeds distally to the level of the bladder neck. The specimen is then transected just distal to the bladder neck, and the vaginal wall is closed longitudinally or transversely using a continuous interlocking stitch with absorbable suture.

## Postoperative care

Patients are managed postoperatively in accordance with the interventions outlined in the enhanced recovery after surgery (ERAS) protocols [34] with the hopes of reducing surgical stress response and optimizing management [35]. Important principles for optimizing ERAS for RARC include early mobilization and sparing use of opiates for analgesia. Nasogastric tubes are not routinely used postoperatively and can be removed in the recovery unit. Oral diet should be started as soon as possible after surgery, as tolerated by the patient. Early ambulation is enforced and patients are followed by both physical and occupational therapy. Prevention of postoperative ileus and promotion of bowel recovery requires a multimodal approach including prokinetic agents (e.g. metoclopramide) and peripherally acting μ-opioid receptor antagonists (e.g. alvimopan) [36].

## Results

Although ORC remains the gold standard for treatment of muscle-invasive bladder cancer and for high-risk recurrent non-muscle-invasive disease [1], the use of RARC has steadily grown following the successful implementation of minimally invasive techniques in management of bladder cancer. Between 2004 and 2010, the percentage of robot-assisted cystectomies increased from 0.6% to 12.8% [37].

Perioperative and postoperative outcomes following LRC and RARC have been well documented and compared with ORC. Current data reveal that LRC and RARC are both associated with reduced estimated blood loss and need for blood transfusion, lower narcotic requirements, and shorter length of stay. A systematic review and meta-analysis done by Tang et al., comparing LRC to ORC, showed that LRC had less blood loss, shorter length of hospital stay, less need of blood transfusion, less narcotic analgesic requirement, shorter time to ambulation, and shorter time to regular diet [6]. Parekh et al. also proposed similar findings in its randomized clinical trial of ORC versus RARC, where it was shown that RARC presented with decreased estimated blood loss (400 ml compared to 800 ml of ORC) and trended toward a decreased rate of excessive length of stay (greater than 5 days) [38]. When compared to ORC, RARC has been shown to have longer surgical time (454.9 vs. 349.1 minutes) [39]. Lastly, a comparison of health-related qualify of life (HRQoL) outcomes for RARC patients versus ORC patients was recently addressed by Messer et al. in their prospective randomized clinical trial of 40 patients from 2009 to 2011 [40]. The study found no significant differences in the HRQoL outcomes using a Functional Assessment of Cancer Therapy–Vanderbilt Cystectomy Index (FACT–VCI) questionnaire preoperatively and then at 3, 6, 9, and 12 months postoperatively [40].

Concerns of oncologic efficacy regarding the use of RARC have been assessed by several studies, with main focus being placed on positive surgical margins (PSMs), lymph node yields, and survival outcomes. PSM after radical cystectomy has been shown to be an independent predictor of metastatic progression as well as decreased

ORC, open radical cystectomy; LRC, laparoscopic radical cystectomy; RARC, robot-assisted radical cystectomy; RFS, recurrence-free survival; CSS, cancer-specific survival; OS, overall survival.

disease-specific survival [41]. The 5-year cancer-specific survival rate after cystectomy for negative surgical margin was 72%, while that of a positive surgical margin was 32% [41]. Nix et al. carried out a prospective RCT in 2010 comparing the oncologic and pathologic outcomes of ORC to RARC in 41 patients and found no significant differences in PSM rates or lymph node yield [13]. Another study by Raza et al. revealed a PSM rate of 8% after RARC [42], which is similar to the PSM rates after ORC (0–10%) reported in several other studies [15, 38, 41, 43–45]. In a retrospective study addressing the recurrence patterns for 383 consecutive patients who either underwent ORC ($n = 120$) or RARC ($n = 263$), Nguyen et al. revealed that no statistical differences existed in terms of local and distant recurrence [46]. Several other studies have further assessed the oncologic outcomes of RARC and LRC in comparison to ORC with regards to their recurrence-free survival (RFS), cancer-specific survival (CSS), and overall survival (OS). A selected few of such studies are outlined in Table 96.1.

## Introduction

Partial cystectomy has emerged as an effective treatment strategy for select patients with muscle-invasive bladder cancer (MIBC). Although early studies assigned a poor oncologic outlook to this management strategy, rigorous patient selection, improvements in surgical technique, and the utilization of multimodal treatment strategies have contributed to substantial improvement in outcomes for MIBC [1–4]. It is currently estimated that between 5 and 10% of patients with MIBC are eligible for partial cystectomy. Enhanced quality-of-life metrics compared with radical cystectomy, specifically preservation of sexual function and voiding patterns, encourage utilization of partial cystectomy in these subgroups. A minimally invasive approach to partial cystectomy offers potential to further enhance perioperative outcomes, including diminished operative blood loss, improved postoperative pain, and shorter hospital stay [5].

## Outcomes

The earliest of series evaluating outcomes after partial cystectomy for MIBC date back to the 1970s. Novick and Stewart described a cohort of 50 patients with muscle-invasive disease in which 5-year cancer-specific survival was less than 50% among patients with MIBC, with the survival rate being less than 20% for those with T3 disease [1]. A similar retrospective review of 45 patients by Schoborg et al. cited recurrence rates as high as 100% and 5-year disease-specific survival of less than 40% among patients with high-grade lesions irrespective of stage [2]. The historically dismal prognosis associated with partial cystectomy, particularly in relation to total extirpative therapy, obscured its utility in the management of muscle-invasive disease until only recently.

A critical review of these reports reveals that the indiscriminate use of partial cystectomy for patients with MIBC is in large part responsible for inferior treatment outcomes. The importance of disease selection has been borne out in several contemporary studies that demonstrate cancer control to have been highly comparable to radical cystectomy [3, 4]. Among patients with a solitary focus of muscle-invasive disease who lack concomitant carcinoma *in situ* (CIS), a matched cohort comparison of both procedures performed by the Mayo Clinic found no significant differences between partial cystectomy and radical cystectomy with respect to 10-year metastasis-free survival (61% vs. 66%, $P = 0.63$) and cancer-specific survival (58% vs. 63%, $P = 0.67$). Overall survival was also found to be similar between treatment groups [3]. These results echo that of a population-based treatment comparison utilizing the SEER database, which demonstrates similar cancer-specific and overall survival for unifocal muscle-invasive disease amenable to complete resection with partial cystectomy [4].

## Indications and contraindications

Success of partial cystectomy for management of MIBC is highly contingent on patient selection and nature of disease. As such, critical review of patient pathology and disease history is of paramount importance when determining eligibility. Among patients without lymph node metastasis or extravesical extension, pathologic features predictive of inferior recurrence-free and cancer-specific survival outcomes include tumor size

>5 cm, need for ureteral reimplantation, and histologic evidence of lymphovascular invasion [6, 7].

Tumor multifocality on initial stages has also been deemed a relative contraindication to partial cystectomy [7, 8]. A review of 86 patients undergoing partial cystectomy for localized MIBC revealed a 3.4-fold higher risk of 5-year cancer-specific mortality in the setting of synchronous lesions compared with unifocal disease [7]. Similarly, the presence of metachronous disease confers a poor oncologic outlook as cancer-specific and recurrence-free survival are reduced approximately threefold in patients with prior history of urothelial cancer [6]. Pathologic evidence of CIS during initial staging generally precludes partial cystectomy due to significant risk for development of intravesicular as well as advanced disease relapse [8]. Prior to planned partial cystectomy, random biopsies of the remaining bladder should be performed to confirm the absence of tumor multifocality or concomitant CIS.

Tumor location is not inherently predictive of oncologic outcomes [8]. Rather, the oncologic efficacy of partial cystectomy is highly dependent on the ability to achieve an adequate negative surgical margin. In this context, solitary tumors on the bladder dome or anterior wall are most amenable to partial cystectomy, whereas lesions situated at the trigone or bladder neck pose a technical challenge of achieving an acceptable disease-free perimeter. No study formally evaluates the optimal extent of a negative surgical margin with partial cystectomy. However, consensus is that resection be performed to achieve a 2 cm margin devoid of malignancy. Tissue from the edge of the resection bed should be sampled by intraoperative frozen section to ensure the absence of residual disease. Positive surgical margins may insinuate a more infiltrative process for which radical cystectomy may be better suited. Lesions in the posterior or lateral wall are technically amenable to partial cystectomy, however, ipsilateral ureteral reimplant may be necessary to enable adequate resection, which invites increased risk for postsurgical relapse [6–8].

A reduction in bladder capacity can be expected after partial cystectomy and may result in urinary frequency or urgency. Eligibility is questionable in patients with severe baseline lower urinary tract symptoms or bladder dysfunction due to risk of exacerbation and perturbed quality of life.

## Bladder-preservation therapy

Data regarding the utility of neoadjuvant chemotherapy prior to partial cystectomy remains scant. Nevertheless, oncologic benefit is inferred based on prospective studies demonstrating a 5% reduction in cancer-specific mortality after radical cystectomy [9]. Preoperative chemotherapy should therefore be considered in all patients eligible for partial cystectomy.

In comparison, chemotherapy has a more established role in alternative forms of bladder-preservation treatment. Trimodality therapy (TMT), which also encompasses maximal transurethral resection and concurrent radiation, is similar to partial cystectomy in that patient selection is of paramount importance to achieve acceptable outcomes. Among medically operable patients, the presence of CIS, tumor multifocality, and hydronephrosis are considered high-risk features and represent relative contraindications to TMT [10, 11]. In addition, large-volume disease that does not lend itself to maximal resection would also preclude TMT [12]. Pooled analyses of trials evaluating the oncologic efficacy of TMT estimated cancer-specific survival and overall survival to be 71% and 65%, respectively, at 5 years and 57% and 36%, respectively, at 10 years [13]. No prospective comparison to radical cystectomy exists. However, several long-term retrospective studies evaluating radical cystectomy and TMT as well as recent studies utilizing national cancer registries demonstrate that radical cystectomy may offer superior cancer-specific survival and overall survival on both multivariable and propensity-matched analysis [12, 14, 15]. However, the differences may be marginal if stringent selection criteria for TMT are applied [16].

Patients being considered for bladder-preservation therapy should be counseled on TMT and partial cystectomy in the appropriate setting. Currently, there are no comparative studies in the literature to evaluate the oncologic efficacy of each treatment. Given the significant overlap in eligibility criteria, advantages and disadvantages of both procedures should be emphasized to facilitate an informed decision. A clear benefit of partial cystectomy is the capacity to perform simultaneous pelvic lymph node dissection, which serves both prognostic and therapeutic value [17]. More accurate pathologic staging of the primary tumor is also possible due to full-thickness resection, again enabling better prognostic stratification as well as the delivery of more tailored adjuvant and salvage therapies. Indeed, a report by Tritschler et al. demonstrated significant risk for pathologic understaging based on imaging alone due to limitations in the capacity of radiologic metrics to gauge local and systemic disease extent [18].

Surveillance is an integral component of both treatment strategies, given early detection of recurrence can optimize cancer control. The incidence of recurrence (both non-muscle-invasive and muscle-invasive) after partial cystectomy is estimated to be 38%, whereas relapse among complete responders ranges between 24 and 43% after TMT [4, 13, 19]. Muscle-invasive recurrence accounts for a relatively small proportion in both groups. The rate of salvage cystectomy is almost 20% after partial cystectomy and as high as 30% with TMT if taking into account the nonresponder cohort [3, 13, 19, 20].

## Minimally invasive partial cystectomy

The advent of the robotic platform has encouraged a paradigm shift in the management of MIBC. Although robotic radical cystectomy is an increasingly utilized treatment option, a recent prospective study demonstrated no difference in pathologic outcomes and clinical metrics, including 90-day complications rate, hospital length of stay, and six-month quality of life [21]. Nevertheless, its non-inferiority may justify constituency in the treatment armamentarium for this disease.

A formal comparison of robotic and open approaches to partial cystectomy remains to be performed. However, several retrospective studies have demonstrated favorable oncologic and perioperative outcomes associated with the robotic technique. The largest of these reviews revealed a 90-day complication rate of 17%, with all having been minor in nature. In addition, median hospital stay in this cohort was only 1 day and median blood loss was only 50 ml [5]. In this context, a robotic approach to partial cystectomy is feasible in patients who meet eligibility criteria for bladder-sparing treatment.

## Patient preoperative evaluation and preparation

A diagnosis of bladder cancer is often prompted by microscopic or gross hematuria. Hematuria workup should ensue and encompasses cross-sectional imaging of the abdomen and pelvis. Cytology should be considered in high-risk patients as the presence of atypical or malignant cells warrants a thorough evaluation for high-grade disease, particularly CIS [22, 23].

Contrast-enhanced computed tomography (CT) remains the ideal imaging study, with emphasis placed on the excretory phase [22, 23]. Regions in the upper urinary that do not demonstrate intraluminal opacification are concerning for a neoplastic process and may be investigated further with ureteroscopy. Filling defects within the bladder may also herald presence of a bladder tumor, however, a more infiltrative process lacking protuberant architecture can present primarily as asymmetrical thickening of the bladder wall. Retrograde pyelography and ureteroscopy for evaluation of the upper urinary tracts should be considered if contrast-enhanced imaging is contraindicated [23].

Cystoscopy is integral to the hematuria workup as it enables direct inspection of the bladder mucosa for tumors and other abnormalities [22, 23]. In the event a tumor is identified, initial mapping of the bladder should be performed to establish focality, size, and location. Tumors should be resected completely, including deep resection into the muscularis to enable accurate clinical staging. Random bladder biopsies can be performed during the initial transurethral resection or second-stage cystoscopy to evaluate for multifocal disease, particularly CIS. Debate exists regarding the utility of prostatic urethral biopsies given that the presence of disease precludes partial cystectomy. Sampling of the prostatic urethra should be considered in the setting of a positive cytology without an identifiable bladder tumor, confirmed CIS within the bladder, or tumor situated at the bladder neck.

If muscle-invasive disease is identified during initial transurethral resection, restaging resection is not necessary unless there exists concern over incomplete resection or the presence of synchronous lesions. Prior to treatment planning, CT of the chest, abdomen, and pelvis should follow to evaluate for systemic disease. Imaging of other organ sites, specifically the brain and bone, is indicated in the presence of symptoms or aberrant serum studies [22, 23].

Patients being considered for partial cystectomy should undergo a comprehensive medical workup which involves obtaining relevant laboratory studies such as basic metabolic profile, complete blood count, liver function tests, and urine culture. Serum creatinine should be optimized as cisplatin-based neoadjuvant chemotherapy should be considered in patients prior to surgical intervention [9]/ A negative urology culture should be documented pre-procedurally to minimize risk of infection.

In addition to discussion of the risks inherent in performing partial cystectomy, patients should be counseled on the possible need for a completion radical cystectomy if more extensive disease is suspected intraoperatively. In this respect, there should be appropriate bowel preparation prior to surgery.

## Operating room configuration and patient positioning

After anesthetic preparations are complete, the patient is secured to the operating table in the dorsal lithotomy position with the hips abducted and arms tucked to the side. The patient should be placed in steep

Trendelenburg to ensure there is no cardiopulmonary compromise. Such position enhances visualization during the transperitoneal approach by shifting intestinal contents cephalad out of the pelvis. The abdomen, pelvis, groin, and perineum are sterilely prepped after which an 18 Fr Foley catheter is placed and included in the sterile field.

Depending on the specific model of da Vinci (Intuitive Surgical Inc., Sunnyvale, CA, USA) system utilized, the robotic tower is positioned between the patient's legs for the da Vinci Si® system or at the side of the operating table for the da Vinci Xi® system. The patient is placed in a steep Trendelenburg position prior to docking the robotic arms to their respective ports.

## Trocar placement

Pneumoperitoneum of 15 mmHg is first established using a Veress needle placed through the umbilicus. For patients with a history of prior abdominal surgery in whom there is concern for adhesions, the Veress needle can be placed in the subcostal location. Low pressures encountered on initial insufflation indicate proper placement of the Veress needle within the intraperitoneal cavity. Six robotic ports are subsequently placed, beginning with the midline camera port approximately 2 cm above the umbilicus or 20–25 cm above the pubic symphysis. A 12 mm port is utilized for the Si system whereas the smaller caliber endoscope of the Xi unit enables use of an 8 mm port. Two 8 mm robotic ports are placed on either side of the midline approximately 8 cm away from the robotic port at the level of the umbilicus. A third 8 mm robotic port is placed on the patient's right side approximately 8 cm lateral to the paramedian robotic port at the level of the umbilicus. Similarly, a 12 mm assistant port is placed 8 cm lateral to left-sided paramedian robotic port. A 5 mm assistant port may be placed in the left upper quadrant at a triangulated distance of 8 cm from the camera port and second robotic port (Figure 97.1).

## Procedure

The bladder is first mobilized by incising the anterior peritoneum lateral to the medial umbilical ligaments (Figure 97.2). The extent of the incision is the vas deferens inferiorly and umbilicus superiorly. The medial umbilical ligaments are subsequently divided, enabling transection of the urachus. The space of Retzius is then developed using a combination of blunt and sharp dissection from cephalad to caudad, allowing the bladder to be mobilized off the anterior abdominal wall (Figure 97.3). Posterior wall tumors may not require full mobilization of the bladder. Instead, the peritoneum can be dissected over its surface, after which the cystotomy can be made.

Flexible cystoscopy is performed by the bedside assistant to identify the tumor site. Transillumination through the bladder helps delineate the initial site of incision so as to avoid violation of the tumor. A longitudinal cystotomy is made and as the bladder is entered, fluid and urine

should be aspirated using a suction device to minimize risk of tumor spillage (Figure 97.4). The Foley catheter and flexible cystoscope are withdrawn and the bladder mucosa is carefully inspected (Figure 97.5). The tumor site should be inspected to ensure the feasibility of obtaining a 2 cm margin grossly devoid of tumor without disrupting the integrity of the ureteral orifices. The presence of satellite lesions should also be excluded (Figure 97.6).

Full-thickness resection of the bladder wall and perivesicular tissue is performed around the tumor site

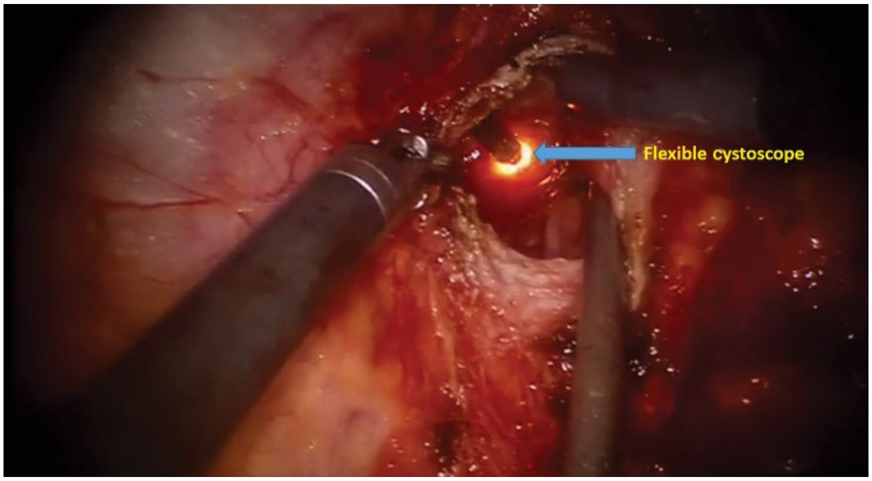

**Figure 97.5** Flexible cystoscopy to facilitation localization of tumor site.

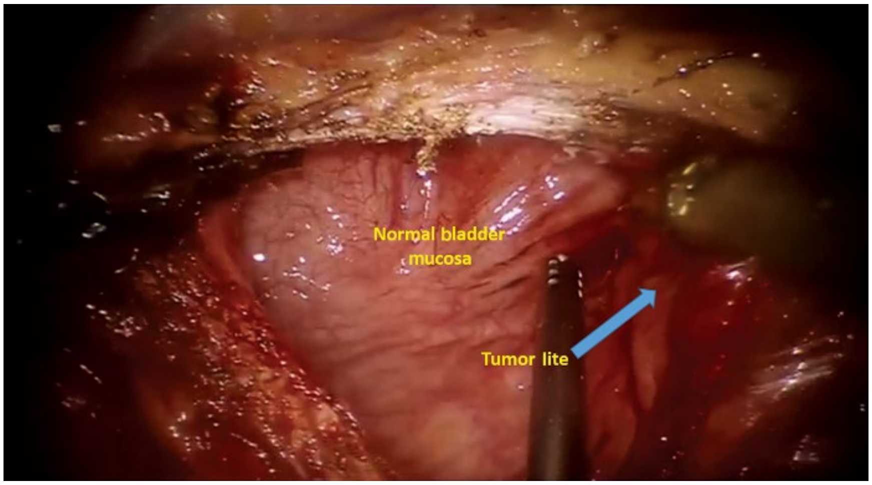

**Figure 97.6** Intraoperative inspection of bladder mucosa to rule out presence of satellite pathology.

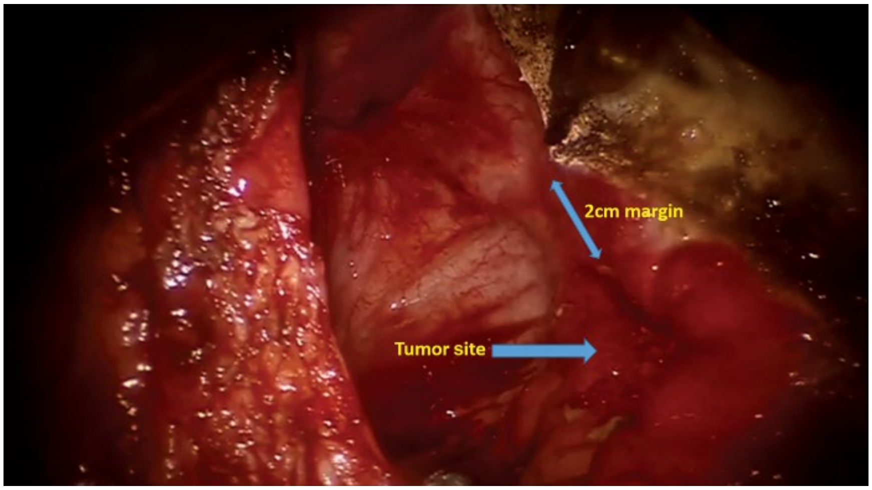

**Figure 97.7** Full-thickness circumferential resection of tumor site with normal parenchymal margin.

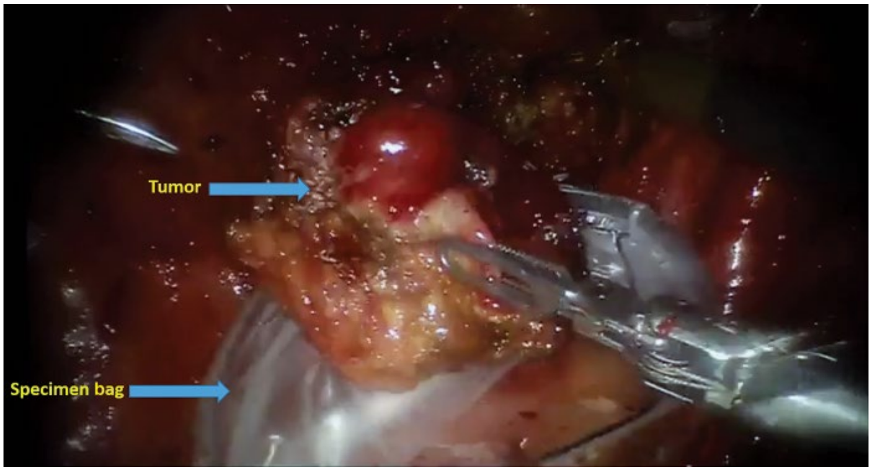
with care taken to obtain a 2 cm margin grossly devoid of tumor (Figure 97.7). The specimen is placed in a 10 mm Endo Catch™ (Covidien/Medtronic, Minneapolis, MN, USA) bag (Figure 97.8). Mucosal and detrusor tissue from the edge of the resection bed are sampled circumferentially by frozen section to evaluate for residual disease (Figure 97.9). Cystorrhaphy is performed only after frozen section analysis confirms the absence of disease. The bladder is closed in a two-layer running fashion using 2-0 polyglactin or 2-0 V-Lok™ (Covidien/



Tumor

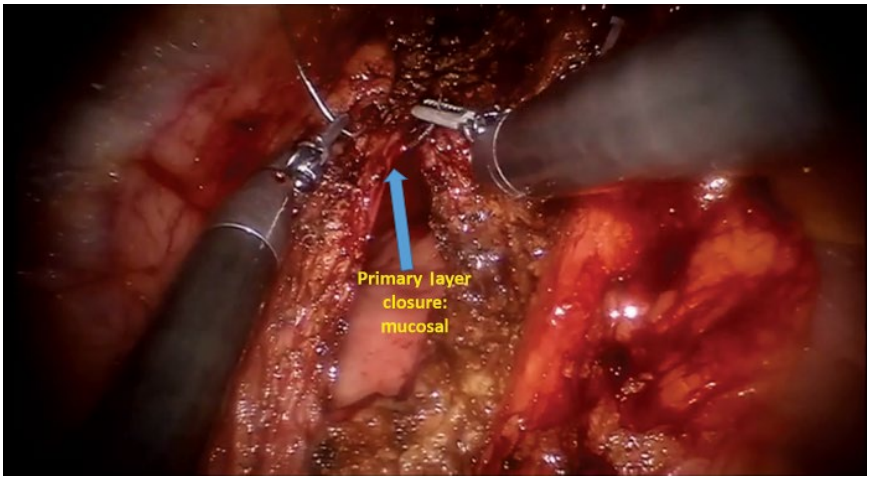
**Figure 97.9** Frozen sections obtained from tissue margins from resection bed.



Primary layer closure: mucosal

**Figure 97.10** Cystotomy closed in two-layer manner, with initial primary closure of bladder mucosa.

Medtronic) suture. Care should be taken to ensure the primary layer incorporates the bladder mucosa (Figures 97.10 and 97.11). The bladder is irrigated with sterile water to assess integrity of the closure. Defects in the suture line should be buttressed with full-thickness figure-of-eight suture. Extended bilateral pelvic lymph node dissection is performed as described elsewhere.

A new 20 Fr Foley catheter is inserted into the bladder and placed to gravity drainage. A 19 Fr Blake drain is positioned in the vicinity of the cystorrhaphy and

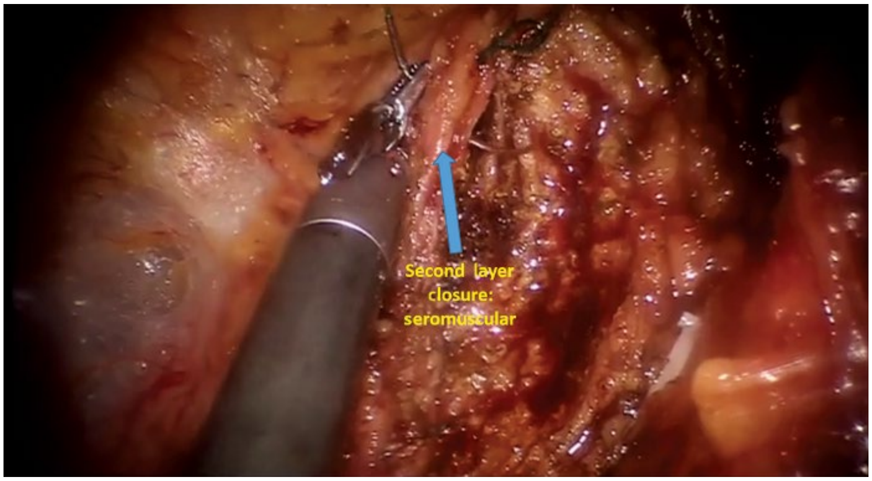


**Figure 97.11** Reapproximation of seromuscular lining of bladder.

brought out to the skin through the right lateral-most robotic port site. The drain is secured to the skin with nonabsorbable suture. Gas insufflation is stopped and the robot is undocked, after which the ports are removed. Specimens are extracted by extension of the midline camera port site. Fascia of the specimen extraction site and the left lateral 12 mm assistant port is closed with figure-of-eight 0-polyglactin suture in an interrupted fashion. Skin incisions are closed with 4-0 monofilament suture.

## Postoperative management

The patient is placed on a clear liquid diet postoperatively until return of flatus, at which point diet can be advanced to regular. Patient-controlled epidural anesthesia may be offered prior to the procedure to facilitate pain control. Early ambulation is critical in enhancing hospital recovery and the prevention of venous thromboembolic events. The Foley catheter is kept to gravity drainage to facilitate healing of cystorrhaphy. Output as well as fluid creatinine from the the pelvic drain helps monitor integrity of the cystotomy suture line. Fluid creatinine may be a more reliable metric to evaluate for urine leak as outputs can be confounded by fluid-shifts due to third-spacing.

Adequate drainage from the Foley catheter and decreasing outputs from the pelvic drain should prompt measurement of fluid creatinine from the pelvic drain. Equivalence between serum and fluid creatinine indicates adequate healing of the cystotomy closure. The pelvic drain may be discontinued the day prior to discharge unless fluid creatinine is found to exceed serum creatinine, in which case the drain should be continued. An outpatient cystogram should demonstrate the absence of contrast extravasation prior to removal of the Foley catheter.

## Surveillance

Postoperative surveillance is critical to optimizing oncologic outcomes after partial cystectomy for muscle-invasive disease. Local disease relapse remains a critical concern after partial cystectomy. Implicit in outcomes being on par with radical cystectomy for select patient groups is the feasibility of controlling intravesical recurrence with salvage therapy. Local recurrence is estimated to occur in 38% of patients, with the majority being non-muscle-invasive in nature. Because of this, transurethral resection and intravesicular instillation of bacillus Calmette–Guérin maintain an important role in preserving the oncologic integrity of partial cystectomy [4].

Although muscle-invasive disease accounts for a relatively small fraction of recurrences, salvage radical cystectomy is necessary in 20% of patients after partial cystectomy [4]. Early recognition is critical as salvage radical cystectomy for organ-confined lesions, which are present in approximately 60% of patients, offers highly favorable disease-free and cancer-specific survival, essentially equivalent to that of primary radical cystectomy. The presence of extravesical extension or lymph node involvement, disease features present in 20% of patients from each group at time of salvage surgery, were poor prognosticators and associated with inferior cancer control when compared with primary radical cystectomy [20]. In this context, the role of close follow-up and early intervention cannot be overemphasized, particularly during the initial 2-year postoperative window when muscle-invasive recurrence is most frequently encountered [4, 20].

Urine cytology and cystoscopy should be performed every three months during the initial 2 years, after which follow-up may be more spaced out. Periodic CT urography is also encouraged to evaluate for upper tract recurrence [22].

## Complications

A key advantage of partial cystectomy is the significant reduction in morbidity and mortality risk relative to radical cystectomy. The incidence of complications after radical cystectomy is estimated to be as high as 70%, with a substantial number being major complications [24]. Comparatively, a review of the National Inpatient Sample observed complications in 16% of patients undergoing partial cystectomy, with complication rates being lowest at high-volume centers. In-hospital mortality after surgery was also significant lower after partial cystectomy [25]. Aside from the risks inherent in any surgical procedure, there are several unique complications inherent to partial cystectomy that require a high index of clinical suspicion.

Urinary leakage across the cystotomy closure may result in the development of a urinoma. High output from the pelvic drain or a drain fluid creatinine that exceeds serum creatinine is concerning for urinary extravasation across the cystorrhaphy. Mild–moderate urine leaks are managed by continuing the Foley catheter for longer duration to facilitate healing of the suture line. Cystogram should be performed prior to Foley removal. The development of a more sizeable urinoma, however, may result in fever, leukocytosis, or abdominal pain. Imaging is necessary if there is suspicion for infected urinoma or pelvic abscess which may require percutaneous drainage. Urinary diversion with bilateral percutaneous nephrostomy tubes should be considered for urinary leaks that are refractory to conservative measures.

Ureteral injury is another recognized complication of partial cystectomy. Care should be taken to avoid the ureteral orifices during tumor resection, particularly given efforts to obtain a wide margin free of tumor. If intraoperative injury is suspected, an attempt should be made to place a ureteral stent in a retrograde manner. Inability to place a stent in this setting warrants ureteral reimplantation at the time of surgery. For lateral wall tumors, preoperative placement of ureteral catheters can be considered. Iatrogenic injury that goes unrecognized may present itself as flank pain, fever, acute kidney injury, or the development of urinoma in the early postoperative period. Cross-sectional imaging, preferably CT urography, should be performed to evaluate for new-onset hydronephrosis or contrast extravasation from the ureter. Disruption in the integrity of the ureter would necessitate an ipsilateral percutaneous nephrostomy tube. Attempt should be made at antegrade stent placement; however, if unsuccessful, a delayed distal ureteral reimplant may be required.

## Introduction

The use of laparoscopic and robotic techniques in the performance of urological procedures has been expanding since the early 1990s. Laparoscopic radical prostatectomy opened the doors for laparoscopic cystectomy, retroperitoneal lymph node dissection, and other complex operations. Radical cystectomy and prostatectomy have been subjected to intense scrutiny and criticism as being inferior to the more traditional open techniques. Robotic prostatectomy, however, has stood the test of time and now over 80% of prostatectomies are performed robotically. Laparoscopic and robotic cystoprostatectomies are on the same path. Early criticism of inadequate lymphadenectomies and poor-quality cancer techniques have been answered and rectified. Each hurdle presented has been well-received and viewed as an opportunity to grow and refine the operation. The very real initial and substantive hurdle was to complete the cystoprostatectomy with a laparoscopic or robotic urinary diversion, completely intracorporeally. Great strides have been made and soon completing the entire operation intracorporeally will be the norm. In this chapter we discuss the history and current state of intracorporeal laparoscopic and robotic ileal loop.

The first intracorporeal ileal loop was accomplished laparoscopically by Kozminski, as reported in the *Journal of Endourology* in 1992. Multiple reports of intracorporeal ileal loops have followed. Since this first effort the early outcomes of improved blood loss, reduced hospital stay, and increased patient satisfaction has encouraged the undertaking of these complex procedures, albeit primarily at large, high-volume academic centers as reported by Gupta et al. [1]. Although extracorporeal ileal conduit has been the traditional mainstay despite the advent of robotic cystectomy, Goh and other have reported on new techniques for intracorporeal urinary diversion described in the literature, such as intracorporeal ileal conduit and intracorporeal continent diversion [2]. Because of such advances, the choice of urinary diversion should no longer be limited by the decision for a robotic-assisted laparoscopic approach.

Many factors are critical to the decision behind intracorporeal ileal conduit creation. These include institutional culture, access to equipment, and knowledgeable support staff. Regardless of approach, radical cystectomy is associated with significant morbidity, mortality, and a complication rate up to 40–70%. Surgeon experience and access to appropriate resources to complete this technical procedure is important. Similarly, patient selection is critical in determining optimal urinary diversion choice. In general, patients with motor or cognitive impairment, chronic renal impairment, or occult malignancy at bladder neck are likely to be better candidates for ileal conduit diversion [3].

Robotic cystectomy with intracorporeal ileal conduit was first described in 2000 by Gill et al., and has since demonstrated excellent long-term outcomes [4]. Since then many small series from single centers have been reported. A retrospective review by Guru et al. of 13 patients, each undergoing intracorporeal or extracorporeal cystoprostatectomy with ileal conduit at Roswell Park Cancer Institute, demonstrated similar mean operative times, blood loss, positive surgical margin rate, and lymph node yields [5]. Other initial reports comparing extracorporeal and intracorporeal ileal conduits suggested higher complication rates and prolonged operative times. However, this was felt to be due to the steep learning curve and ongoing technique mastery. Rahman et al. reported their experience in nine patients [6]. They used the Wallace technique for the uretero-ileal anastomosis

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.
© 2019 John Wiley & Sons Ltd. Published 2019 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/smith/textbookofendourology

and reported excellent outcomes. The operative times, although somewhat variable, were felt to be acceptable (compared to open norms). None of the patients needed to be converted to open surgery. Patients were discharged within 7 days, although the authors point out they could have left the hospital sooner but needed to stay longer for ostomy nurse education etc. All patients returned to full normal activities within two weeks.

Bishop et al. reported their experience with eight intracorporeal ileal loop diversions in 2013 [7]. Again, patients recovered quickly with significantly lower postoperative pain levels and rapid return of normal bowel function. All patients were able to be discharged in less than a week. An analysis of the International Robotic Cystectomy Consortium retrospective data between 18 institutions and 935 patients revealed 787 extracorporeal urinary diversions (75% of which were ileal conduits) and 148 intracorporeal diversions (of which 59% were ileal conduits). Their results found no difference in operative times between extracorporeal urinary diversion and intracorporeal diversion, but did note lower blood transfusion rates and 90-day readmission rates in favor of intracorporeal diversion. In addition, intracorporeal diversion was associated with significantly lower gastrointestinal complications [8]. However, no subset analysis was completed for extracorporeal versus intracorporeal ileal conduits only. Other small series have also shown the ability and usefulness of this procedure and the learning challenges experienced [9–11].

The largest series by a single institution was reported by Azzouni et al. in 2013 [12]. They reported on 100 patients with intracorporeal ileal loop using the “marionette” technique. In this technique, after the ileal loop is created it is suspended at the distal end to the abdominal wall by a suture passed through the abdomen on a Keith needle and then through the loop. By moving the suture up and down (much like a puppeteer or marionette) the loop can be controlled or moved to facilitate an easier uretero-ileal anastomosis. Others use this technique and find it very helpful. The authors report total operative time for the cystoprostatectomy, node dissections, and loop creation of just under 6 hours, which is very reasonable. The ileal loop creation was generally 2 hours, although in our experience we have found that as the surgeon moves up the experience curve the time to create the loop can be reduced to 90 minutes or less. Azzouni et al. also report an 81% overall complication rate at 90 days. About 60% or so were infections (urinary tract infections etc.) and gastrointestinal disorders (small bowel obstruction, *Clostridium difficile* enteritis, etc.). At 90 days 85% of the complications were Clavien $\leq$ II level and 15% $\geq$ Clavien III. The mortality rate was 1% in a patient who expired secondary to myocardial infarction. The 30-day readmission rate was 16%.

This important series has shown that complete intracorporeal ileal loop creation is reasonable, rational, safe, and can be completed in an acceptable time (as compared to the standard open techniques). Its use will continue to grow as urologists gain more experience and through young urologist graduates with the necessary skills gained in residency.

The perceived advantage of intracorporeal ileal conduit is thought to be secondary to avoidance of mini-laparotomy incision and, as a result, reduced bowel handling and exposure. In addition, the intracorporeal approach enables the surgeon to make uretero-ileal anastomoses at the physiologic location in the ileal loop where they will lie post procedurally, likely resulting in less tension and mobilization required. Less handling and mobilization of the ureter are felt to create fewer issues with ureteroenteric stricture. Regardless of intracorporeal or extracorporeal diversion type, robot-assisted radical cystectomy has been shown to be associated with similar oncologic outcomes. This is likely secondary to the fact that the oncologic portion of procedure is completed first, prior to diversion, and has been corroborated in the literature, demonstrating no significant differences in positive surgical margin rates, lymph nodes or cancer-specific or overall survival rates [12].

As surgeon experience improves, the volume of robot-assisted cystectomies with intracorporeal diversions will likely increase. Early results from the literature support decreased complication rates and reduced length of stay, and risk of conversion to open surgery decreases as surgical volume and experience improve [13]. Techniques such as colored stay sutures and bowel detubularization tools are already being published in the literature as techniques to improve operative efficiency [14, 15].

## Technique for robotic intracorporeal ileal conduit

All patients undergoing robotic cystectomy and intracorporeal diversion follow an enhanced recovery pathway that is initiated 24 hours prior to surgery. Patients are instructed to consume clear liquids and a high-calorie carbohydrate load the day before surgery. In the pre-op area, patients receive a μ-opioid antagonist to optimize bowel function. A site for the ileal conduit is selected with the assistance of an ostomy care nurse prior to induction of anesthesia.

The authors employ a standard six-port robotic cystectomy configuration for performance of the cystectomy as well as intracorporeal ileal conduit. The assistant stands on the left side of the patient. Placement of the assistant ports on the left abdomen facilitates bowel stapling directed toward the right lower quadrant.

After completion of robotic cystectomy and extended lymph node dissection, the ileal conduit is developed. Atraumatic double-fenestrated graspers are used for bowel manipulation. The ileocecal valve is identified and at least 15 cm of terminal ileum is spared. The distal segment of the ileal conduit is divided using a 60 mm bowel load stapler (staple height 3.5 mm thickness). The bowel segment for the conduit is then measured from the sacral promontory to the previously marked stoma site at the abdominal wall generally measuring 15–17 cm in length. The proximal division of bowel is then performed.

After segmentation, a standard side-to-side bowel anastomosis is performed using a 60 mm bowel load stapler. The antimesenteric sides of small bowel are joined, and then the anastomosis is completed with a perpendicular fire of the bowel stapler.

The uretero-ileal anastomoses are performed using a Bricker anastomosis with minimal handling of the ureter. Other approaches have described a Wallace technique for ureteral anastomosis. The left ureter is transposed under the sigmoid mesentery. The uretero-ileal anastomoses are performed at the proximal end of the conduit in a dependent manner. The anastomosis is performed using 4-0 Vicryl in a running fashion. Single-J stents are placed percutaneously through a small 2 mm port placed over the loop only for that purpose. We gently slide the double-fenestrated grasper down the open end of the loop to pull the free ends of the stents to the distal loop. The free ends emanate from the stoma of the conduit. The distal end of the conduit is then delivered through the previously marked stoma site and matured to the skin in the standard fashion.

# Laparoscopic/Robotic Continent Diversion

*Christopher R. Reynolds & Ashok K. Hemal*

*Wake Forest Baptist Medical Center and Wake Forest School of Medicine, Winston-Salem, NC, USA*

## Introduction

For patients undergoing robot-assisted radical cystectomy (RARC), continent urinary diversion is a surgical option that may provide for better cosmesis and quality of life. As the utilization of RARC for the treatment of muscle-invasive bladder cancer has increased over the last decade, minimally invasive continent urinary diversion has become a feasible and safe alternative to the open procedure. The general advantages of laparoscopic surgery and robot-assisted laparoscopic surgery, including reduced morbidity, quicker recovery time, improved visibility, and reduced blood loss, have driven interest and advancement in minimally invasive surgery. Potential benefits specific to minimally invasive continent urinary diversion include less manipulation of bowel with quicker return of bowel function, reduced pain, and less morbidity from incisions.

Advances in minimally invasive radical cystectomy and urinary diversion occurred stepwise in the preceding decades. The first laparoscopic radical cystectomy with extracorporeal ileal conduit was reported in 1995 [1]. This was followed by the first described laparoscopic radical cystectomy with intracorporeal ileal conduit in 2000 [2]. Laparoscopic radical cystectomy with intracorporeal ileal neobladder was first reported in 2002 [3]. Initial obstacles to minimally invasive radical cystectomy and urinary diversion included the limited maneuverability of laparoscopic tools, a steep learning curve, and long operative times.

Since the US Food and Drug Administration (FDA) approval of the da Vinci Surgery System in 2000, wristed laparoscopic instruments and other advancements have allowed urologists to overcome many of the limitations of conventional laparoscopic surgery. The first case report of RARC with completely intracorporeal urinary diversion was described in 2003 [4]. In a seminal report in the same year, RARC with extended pelvic lymph node dissection and urinary diversion was described in 17 patients [5]. Three patients received ileal conduit urinary diversion and 14 received orthotopic neobladders in a hybrid approach. The orthotopic neobladder (ONB) was constructed extracorporeally through the specimen extraction site, and the urethral-neobladder anastomosis was performed robotically after placing the neobladder back in the abdomen and closing the incision. RARC and urinary diversion was described in three female patients in 2004 [6]. Review of initial RARC and urinary diversion cases showed that the procedure could be performed with relatively short operative time, low blood loss, and safely without intraoperative complications [7]. Multiple case series have since demonstrated the safety of RARC and completely intracorporeal ONB [8–16]. RARC and urinary diversion has also been shown to have oncologic outcomes equivalent to open radical cystectomy [17]. Robotic continent cutaneous urinary diversion has only recently entered the repertoire of the robotic surgeon after its first description in 2015 [18].

Probably owing to the numerous perceived disadvantages of a minimally invasive approach, including the technical difficulty, longer operative time, and increased cost, urologists have been slower to adopt minimally invasive urinary diversion than other robot-assisted urologic procedures. Despite perceived disadvantages, RARC with intracorporeal urinary diversion is being performed with increasing frequency. Based on data published by the International Robotic Cystectomy Consortium (IRCC), 7% and 11% of 935 patients undergoing RARC between 2003 and 2011 had a completely intracorporeal neobladder or ileal conduit, respectively [19].

## Indications and contraindications

All patients who are candidates for radical cystectomy should at least be considered for laparoscopic or robotic continent diversion. Prior abdominal surgery, radiotherapy, obese body habitus, advanced age, poor functional status, and certain medical conditions such as poor pulmonary compliance may preclude a minimally invasive technique. Candidates for continent urinary diversion also need to be physically and intellectually able to perform scheduled voiding and urethral catheterization if necessary.

For ONB, patients should have a patent urethra, an absence of stress urinary incontinence, and an absence of tumor in the urethra distal to the prostate in men and in the bladder neck in women. Preoperative biopsy and/or intraoperative frozen section should be performed if indicated. ONB is contraindicated in patients with chronic kidney disease with serum creatinine of greater than 2 mg/dl or GFR <40 ml/min/1.73 $m^2$. However, if significant recovery of renal function is anticipated with alleviation of renal obstruction by urinary diversion, an exception can be made. Cirrhosis is a contraindication to ONB as reabsorption of ammonia can lead to hyperammonemia. Inflammatory bowel disease, short bowel disease, and extensive abdominal/pelvic radiotherapy are also contraindications to ONB.

## Preoperative evaluation and preparation

The preoperative evaluation of patients undergoing robotic/laparoscopic continent diversion begins with a thorough history and physical examination. Patients should have medical clearance, especially if the American Society of Anesthesiology (ASA) class is III or greater. Assessment of renal function, and metabolic and hematologic abnormalities are carried out with laboratory studies. A preoperative urine culture is obtained, and preoperative antibiotic prophylaxis is administered as indicated. If radical cystectomy is being performed for malignancy, staging studies including chest X-ray or thoracic computed tomography (CT) scan and abdominal and pelvic CT scan are conducted. Bone scan is performed only if metastasis to the skeleton is suspected, such as with elevated alkaline phosphatase or bone pain. All patients being considered for radical cystectomy for malignancy should have referral to an oncologist for possible neoadjuvant chemotherapy.

In all cases, patients need marking for the potential of a conduit or catheterizable stoma. Mechanical bowel prep is not recommended as there has not been any clearly demonstrated benefit, and mechanical bowel prep can cause electrolyte abnormalities [20]. The day prior to surgery, patients are prescribed a clear liquid diet and are to be nil per os from the midnight before surgery. Also in the preoperative period, patients can be given instruction in clean intermittent catheterization.

### Operating room configuration and patient positioning

The patient is placed in the supine position. Prophylactic heparin or low molecular weight heparin is given before surgery. General endotracheal tube anesthesia is administered, and a broad-spectrum antibiotic is given to cover enteric organisms. An oro- or nasogastric tube is inserted to decompress the stomach. A urethral catheter is inserted and left to gravity drainage. The patient is then placed in the dorsal lithotomy position with arms tucked. The extremities are padded carefully to avoid neuropraxia and compartment syndrome. If RARC is being performed, the patient is moved into a steep Trendelenburg position (30–45°), which facilitates movement of the bowels out of the pelvis. With ONB construction, Trendelenburg position is reduced to 10–15°, or the patient can be placed in the supine position, and the robot can be side-docked to avoid potential complications from a prolonged lithotomy position. After patient positioning, the skin is shaved with a clipper, and a sterile field is created by prepping the perineum, genitals, proximal thighs and the infraxiphoid abdomen and pelvis.

Instrumentation required for RARC with ONB is listed in Box 99.1.

### Trocar placement

#### The da Vinci S and Si robotic systems

The abdomen is insufflated to 15 mmHg utilizing a Veress needle. A 12 mm bladeless trocar is inserted about 5 cm above the umbilicus. The camera is inserted, and the abdomen is inspected for iatrogenic injury, adhesions, and metastatic disease. Three 8 mm robotic ports are then placed under direct visualization (Figure 99.1a). Two robotic ports are placed 7–10 cm lateral and cephalad to the umbilicus. A additional robotic port is placed in the right lower quadrant of the abdomen 7–10 cm lateral to the right-sided robotic port and 5–7 cm superior to the iliac crest. A 12 mm AirSeal trocar (ConMed, Utica, NY, USA) is placed in the left abdomen 5–7 cm superior to the iliac crest. Positioning of the assistant port in the left abdomen and fourth robotic arm on the right side aids with bowel manipulation and the avoidance of acute-angle stapling.

- 5 mm long Stryker suction tip (Stryker)
- Small, large, and extra-large laparoscopic Hem-o-lok appliers (Weck Closure Systems, Research Triangle Park, NC, USA)
- Three 8 mm cannulas with obturator and seals (Intuitive Surgical Inc.)

**Disposable instrumentation**

- Basic accessory kit and drapes (Intuitive Surgical Inc.)
- Camera head (Intuitive Surgical Inc.)
- 0° and 30° endoscopes (Intuitive Surgical Inc.)
- StrykeFlow 2 suction/irrigation system (Stryker)
- Echelon Flex Powered Endopath Stapler (Ethicon Endo-Surgery)
- Large and extra-large Hem-o-lok clips (Weck Closure Systems)
- Veress needle (Ethicon Endo-Surgery)
- One Endopath Xcel 12 mm bladeless bariatric trocar for camera port (Ethicon Endo-Surgery)
- One Endopath Xcel 12 mm bladeless trocar (Ethicon Endo-Surgery)
- One Endopath Xcel 15 mm bladeless trocars (Ethicon Endo-Surgery)
- Endo Catch II 15 mm Specimen Pouch (Covidien, Norwalk, CT, USA)
- Two extra-large Hem-o-lok clips prepared with suture attached (Weck Closure Systems) for clipping and tagging of the ureters

**Optional instrumentation**

- ProGrasp forceps (Intuitive Surgical Inc.)
- 0 Vicryl on CT-1 needle (Ethicon, West Somerville, NJ, USA)
- Echelon Endopath 45 mm Stapler (Ethicon Endo-Surgery)
- 1-0 V-Loc 90 (glycolic acid–trimethylene carbonate, Covidien) for vaginal reconstruction
- Harmonic ACE curved shears 8 mm (Ultrasonic Energy Instrument, Intuitive Surgical Inc.)
- Large robotic clip applier (Intuitive Surgical Inc.)
- EndoWrist One suction/irrigator (Intuitive Surgical Inc.)
- EndoWrist vessel sealer (Intuitive Surgical Inc.)
- EndoWrist stapler (Intuitive Surgical Inc.)
- LigaSure Atlas (Covidien)
- Enseal tissue sealing device (Ethicon Endo-Surgery)
- Silicone vessel loops (Aspen Surgical Products, Caledonia, MI, USA)
- Endo GIA Ultra universal stapler (Covidien)
- Lapro-Clip (Covidien)
- Firefly near-infrared fluorescence visualization system (Novadaq Technologies, Mississauga, Ontario, Canada)

If conversion to an ileal conduit is likely, a second assistant port can be inserted in the prospective stomal site between two robotic ports. Stapling of the pedicles in RARC is facilitated by placement of a 12 mm robotic port near the midline. A robotic stapler may be utilized through this port.

For RARC, Hot Shears (Intuitive Surgical Inc., Sunnyvale, CA, USA) are used in the right robotic arm, PK dissecting forceps (Gyrus ACMI PK, Gyrus ACMI, Norwalk, OH, USA) in the left robotic arm, and Prograsp or Cadiere forceps (Intuitive Surgical Inc.) in the third robotic arm. For intracorporeal ONB, two needle drivers are needed. A 30° down lens aids with dissecting deep in the pelvis and for extended pelvic lymph node dissection. A 30° up lens is helpful for dropping the bladder, dissecting behind the prostate, and for facilitating increased urethral length in the retro-apical dissection. A 0° camera lens is used for the apical dissection and the urethral-neobladder anastomosis.

### The da Vinci Xi robotic system

As with the Si and S robotic systems, six ports are utilized (Figure 99.1b). With the Xi system, an 8 mm universal camera–robotic port is used instead of a 12 mm camera

port. A notable advantage to the Xi system is that it facilitates ONB creation with greater ease in the supine position, which decreases the risk of positioning-related complications. A 12 mm robotic port can be placed instead of an 8 mm robotic port for the medial right robotic arm. A robotic or laparoscopic stapler can then be utilized from this site. This site can be converted to 8 mm when not in use for stapling.

Accessories that may be utilized for Si and Xi robotic systems during RARC with urinary diversion include the EndoWrist One Vessel Sealer and the EndoWrist Stapler (Intuitive Surgical Inc.). The EndoWrist One Vessel Sealer may be used for ligating small vessels and mesentery while the EndoWrist Stapler may be employed instead of a laparoscopic stapler.

### Laparoscopic

Six ports are utilized for laparoscopic radical cystectomy with intracorporeal ONB creation (Figure 99.2). A 10–11 mm camera port is placed above the umbilicus. Two 12 mm ports are placed on the left and right lateral edges of each rectus muscle just inferior to umbilicus. A 10 mm port is placed in the left iliac fossa. A 5 mm port is placed on the right at the level of the anterior superior iliac spine. A 5 mm port is placed between the umbilicus and pubic symphysis.

## Procedure

Different options are available for minimally invasive continent urinary diversion, including ONB, continent cutaneous urinary diversion, and, if no other option is available, a cutaneous ureterostomy. Various techniques for robot-assisted ONB have been described and may be performed based on surgeon preference. Different types of ONB have been reported. Initial neobladder types constructed in a hybrid procedure included the W-pouch and T-pouch [5]. Neobladder types that have been routinely constructed completely intracorporeally include the Studer pouch [9, 10], W-pouch [15], U-pouch [8], and pyramid neobladder [14]. The most popular type constructed intracorporeally is the Studer neobladder.

### Hybrid technique of neobladder construction

In this technique, the neobladder is constructed outside the abdomen, placed back in the abdomen, the incision is closed, and anastomoses between the neobladder and ureters and urethra are performed robotically. Before undocking the robot for extracorporeal neobladder construction, certain steps are conducted to aid with robotic intracorporeal anastomoses. Vicryl or barbed suture is placed at the 3, 6, and 9 o'clock positions of the urethra. The ureters are clipped and tagged with dyed and undyed suture to help distinguish each. A silk suture or vessels loop is used to mark the distal end of the segment of ileum to be selected for neobladder formation at a point 15 cm from the ileocecal junction. The left ureter is then transposed to the right side under the sigmoid mesentery. A 20 Fr Foley catheter is inserted in the urethra. Specimens and anchoring sutures are secured to the abdominal wall with Hem-o-lok® (Weck Closure Systems, Research Triangle Park, NC, USA) clips or to a grasper at the medial-most port site to facilitate easy retrieval and identification after the midline incision is made. The robot is then undocked, and a 5–6 cm incision is extended from the inferior aspect of the midline camera port. The surgical specimen is removed and the ureters are oriented appropriately using the suture markings. The terminal ileum is identified and the neobladder is constructed.

For the uretero-neobladder anastomosis, ureteral positioning is confirmed within the pelvis prior to anastomosis. The anastomosis can be completed with the Bricker technique with 5-0 Monocryl suture or 4-0 Vicryl suture if braided suture is preferred.

Several options are available for the urethral-neobladder anastomosis. In one technique, the posterior anastomosis is carried out using the 3, 6, and 9 o'clock urethral sutures. The anastomosis is then continued to the anterior midline in a running fashion. Another technique for intracorporeal robot-assisted anastomosis involves a hemi-circumferential anastomosis. In the clockwise direction, the suture needle is passed outside-in at the 5 o'clock position on the neck of the neobladder, then inside-out on the urethra up to 11 o'clock position. A second suture is started outside-in on the urethra and then inside-out on the neobladder at the 7 o'clock position. The anastomosis continues until complete in the counterclockwise direction.

The uretero-neobladder anastomosis can also be performed extracorporeally.

### Pure intracorporeal ileal studer neobladder (see Video 99.1)

Ileum is generally preferred for construction of the neobladder, though sigmoid colon may also be utilized if use of ileum is contraindicated.

### Bowel isolation

A 60 cm segment of distal ileum is selected, starting 15 cm proximal to the ileocecal junction. The segment is identified and then marked. Two red vessel loops are placed through the mesentery to mark the distal end of the selected bowel segment, and two blue vessel loops are placed in the mesentery to mark the proximal end of the segment. Use of vessel loops in the mesentery assists with bowel manipulation. Bowel is measured using a sterile flexible tape measure, premeasured silk suture, or a premeasured open-ended ureteral catheter. Cadiere forceps are used on the right and fenestrated bipolar forceps on the left for manipulation of the bowel.

Mesenteric angiography can be obtained by using the Firefly visualization system (Novadaq Technologies, Mississauga, Ontario, Canada) with the robot after administration of 2–5 ml of 2.5 mg/ml unconjugated indanocyanine green [22]. This step helps to preserve the blood supply to the neobladder and precludes the need for intracorporeal backlighting of the mesentery, which can be awkward. The distal end of the selected ileal segment is transected with a 60 mm laparoscopic stapler via the 12 mm left assistant port and a blue stapler load (3.5 mm thickness). The distal mesenteric window is opened further using white vascular stapler loads. This step is important, as it facilitates mobilization of the reservoir into the pelvis. Vessel loops help with manipulation of the bowel. The transected distal bowel segment is marked with a red vessel loop in the mesentery and a purple-dyed 3-0 Vicryl suture. The ileal segment is marked at the 25 cm point with undyed suture to mark the apex of the posterior apical plate of the neobladder. The 50 cm point is marked with undyed suture to designate the beginning of the afferent limb. The proximal end of the ileum is transected, and another purple-dyed 3-0 Vicryl suture is placed to mark the proximal end of the isolated ileal segment.

### Ileoileal anastomosis

Importantly, the anastomosis needs to be carried out cephalad to the isolated ileal segment to allow for mobilization of the neobladder into the pelvis. Bowel segments are brought in apposition, and a side-to-side ileoileal anastomosis is carried out using a 60 mm laparoscopic stapler. The stapler load is applied on adjacent antimesenteric bowel walls. Vessel loops are used in this step to place the bowel on traction. The open end of the anastomosed bowel is then closed with the 60 mm laparoscopic stapler by applying a transverse stapler load. Alternatively, an end-to-end ileoileal anastomosis can be made with interrupted 3-0 Vicryl suture.

#### Detubularizing the bowel

The previously placed undyed suture at the 25 cm mark of the isolated bowel segment is grasped by the fourth arm and brought down into the pelvis. The two 25 cm ileal segments are brought adjacent to each other symmetrically. The additional 10 cm of ileum is used as an afferent limb. The distal 50 cm of the excluded ileal segment is then detubularized by making an incision on the antimesenteric side over a 24 Fr red rubber catheter, chest tube, or without an intraluminal tube.

#### Posterior plate of the neobladder

Apposing edges of the posterior wall of the neobladder are approximated with 2-0 absorbable interrupted sutures at 6–8 cm intervals; 6 cm tags are left for bowel manipulation. The posterior wall is then closed with a running suture in a watertight fashion with 2-0 barbed suture. After the posterior plate is completed, a 3-0 barbed suture is placed at midpoint of the right side of posterior plate at the point of the future urethral-neobladder anastomosis.

#### Urethral-neboladder anastomosis

The posterior plate is rotated 90° counterclockwise with caudal traction. The anastomosis is made with the previously placed barbed suture in a running fashion. The posterior section of the anastomosis is carried out over a 24 Fr hematuria catheter. The anterior portion of the anastomosis is completed with interrupted sutures or continuing to run the posterior sutures.

Maneuvering the ileum into the pelvis for the urethral-neobladder anastomosis can be challenging. Tricks that may help include using a Penrose drain inserted in the ileal mesentery as a handle to provide traction via the fourth robotic arm in the direction of the urethral stump. The seromuscular layer of the neobladder may be sutured to the rectourethralis muscle with a barbed suture to keep the urethra in close proximity to the neobladder neck. Releasing the peritoneum over the mesentery of the neobladder, stapling the proximal region of the mesentery of the neobladder without compromising the blood supply, and dissecting around the ileum around the ileocecal junction may also help.

#### Uretero-neobladder anastomosis

The distal ends of the ureters are spatulated. Each ureter is anastomosed to the afferent limb of the neobladder using the Bricker technique with 5-0 Monocryl suture in an interrupted or running fashion. A Vicryl stitch may be used to bolster the anastomosis and maintain orientation.

Prior to completing the uretero-neobladder anastomosis, each ureter is intubated with a 6 Fr 30 cm double-J (JJ) ureteral stent which can be inserted through one of the previously placed assistant ports or through a 2 mm port in the right iliac fossa. The stents are to be completely internalized. The additional length of the stents helps with cystoscopic retrieval.

Alternatively, a Wallace technique can be used for the uretero-neobladder anastomosis. The medial wall of the spatulated ureters are sewn together before this is anastomosed to the afferent limb of the neobladder in an end-to-side manner.

#### Closing the neobladder

The posterior plate of the neobladder is cross-folded on itself and the midpoint is fixed with a horizontal mattress stitch. The anterior wall of neobladder is closed with a running 2-0 barbed suture. A suprapubic tube, which is optional, can be placed through a small opening along this suture line. Suprapubic tube placement through the anterior neobladder wall helps with fixing the neobladder to the anterior abdominal wall, which can facilitate future percutaneous procedures if indicated. The neobladder is then irrigated by transurethral Foley catheter to ensure there is a watertight closure. Leaks are closed with 2-0 Vicryl suture. The surgical specimen is extracted through an opening in the vagina in women or through an extended incision at the midline camera port site in men. A closed-system suction drain is then placed in the abdomen via a lateral port site.

#### Abdominal wall closure

Any port site 10 mm or greater is closed with 1-0 Vicryl suture at the fascia. Fascia at the specimen extraction site is closed with figure-of-eight polydioxanone (PDS), and Scarpa's fascia is closed with running Vicryl suture. The skin is closed with subcuticular 4-0 Monocryl suture, and Dermabond (Ethicon, Cincinatti, OH, USA) or a sterile surgical dressing is applied.

There are different variations to intracorporeal neobladder construction. Wiklund et al. complete the urethral-neobladder anastomosis at the beginning of the procedure after isolation of an ileal bowel segment [9]. The proximal anterior portion of the neobladder is left open after closing the anterior portion of the neobladder, and the ureteral-neobladder anastomosis is performed with a Wallace technique.

Gill and colleagues have improved operative times in intracorporeal neobladder creation and have detailed modifications to the University of Southern California (USC) protocol [23]. In this update, 60 cm of ileum is used for construction of the neobladder, 44 cm is utilized for the reservoir, and the remaining 16 cm is used for the afferent limb. A 5 cm segment of bowel proximal to the afferent limb is discarded. This step may help prevent neobladder–enteric fistula by providing more separation between the neobladder and bowel anastomosis. Bowel measurement starts with identification of the most dependent loop of terminal ileum. This region, which is to become the site of the future urethral-neobladder anastomosis, is marked with a suture. A premeasured 11 cm suture is utilized to measure out the ileum from this marking. All markings on the urinary diversion are performed with undyed suture, and all markings of the bowel ends of the future ileoileal anastomosis are made with blue suture. Color coordination of sutures markings helps avoid any confusion and errors in the bowel anastomosis resulting from a limited field of vision. Prior to performing the urethral-neobladder anastomosis, the previously placed suture on the ileal side of the future urethral-neobladder anastomosis is sutured posterior to the urethra at the cut edge of Denonvilliers' fascia to reduce tension at the urethral-neobladder anastomosis. The urethral-neobladder anastomosis is carried out in a running fashion with a double-armed 3-0 Monocryl suture on an RB-1 needle starting at the 6 o'clock position. Alternatively, a 3-0 barbed suture can be used if there is minimal tension on the anastomosis.

## Robot-assisted continent cutaneous urinary diversion

Continent cutaneous urinary diversion is another option for patients who may not be candidates for ONB and was recently described [18].

### Patient positioning and port placement

The robot is undocked after RARC, and the patient is placed in a modified lateral position. Three additional ports are placed in addition to those previously described for RARC (Figure 99.3).

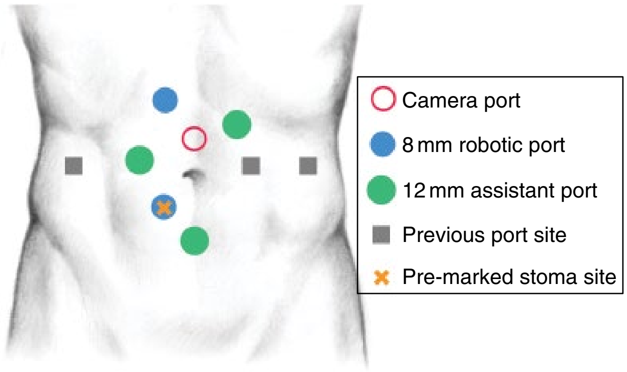

Figure 99.3 Port placement for side-docking for continent cutaneous urinary diversion.

### Bowel isolation

The robot is then brought over the patient's right side. Cecum and ascending colon are mobilized. The colon is mobilized beyond the hepatic flexure to the midtransverse colon, and a 30 cm segment of ascending colon is measured. Bowel is manipulated using double-fenestrated bowel graspers. A laparoscopic stapler is introduced via the midline 12 mm assistant port and is used to transect the large bowel. A 10 cm section of small bowel is measured from the ileocecal valve, and small bowel is divided using the left upper quadrant assistant port.

### Ileocolonic anastomosis

A side-to-side ileocolonic anastomosis is performed with two stapler loads. The anastomosis is made by first inserting the stapler through the right lateral assistant port and applying the stapler load to connect the small bowel to the colon. The open end is then closed with a stapler load applied transverse to the first staple line after reinsertion of the stapler through the midline assistant port. Vicryl suture is used to reinforce the anastomosis.

### Detubularizing the bowel

The stapled end of the isolated bowel segment is removed. Colon is detubularized along the entire antimesenteric side of the colon, starting from the previously stapled end.

### Ureterocolonic anastomosis

The left ureter is transposed under the sigmoid mesentery to the right side. A 1 cm hiatus is made for each ureter on the posterior side of the pouch. Ureters are passed from outside the pouch to in, and a Bricker anastomosis is carried out with two 4-0 Vicryl sutures.

A 2 mm port is used for percutaneous stent placement. Two 7 Fr single-J ureteral stents are utilized.

### Closing the pouch

The open end of the pouch is folded over and approximated at the midline with 2-0 Vicryl suture. Appendectomy is performed, creating a cecostomy. Stents are externalized through the cecostomy. The pouch is then closed in a running fashion with barbed absorbable suture. A suprapubic tube is then passed through the cecostomy alongside the stents, and suprapubic tube and ureteral stents are secured within using a purse-string suture. The pouch is irrigated through the suprapubic tube to ensure a watertight closure.

### Tapering of the efferent limb

The robot is undocked and surgical specimen extracted through an extended incision at the camera port site. Through the extraction site, the ileal efferent limb is tapered over a 14 Fr catheter using a surgical stapler. Interrupted 2-0 silk sutures are used to reinforce the ileocecal valve over the catheter. The efferent limb is brought out through stoma site, and the end is matured and sutured to the skin. Stents and suprapubic tube are externalized via the right-sided assistant port. A surgical drain is placed through the right robotic assistant port

### Robot-assisted ureterosigmoidostomy

Robot-assisted ureterosigmoidostomy may be considered if other forms of diversion are contraindicated. Ureterosigmoidostomy should be a last resort, as severe electrolyte disorders, urinary tract infections, and significantly increased risk of colon cancer are common postoperative issues.

### Laparoscopic continent urinary diversion

Gill and colleagues were the first to report on the laparoscopic technique [3]. Similar steps are used in performing the laparoscopic procedure. However, modifications in steps are required due to different equipment and port placement and the ergonomic limitations encountered with laparoscopic tools. Several steps can be adapted from robot-assisted surgery to make the procedure more versatile.

## Postoperative management

The postoperative management of patients undergoing minimally invasive continent urinary diversion is similar to that for open surgery. Early mobilization is vital to prevent deep venous thrombosis, pneumonia, and patient debility. Patients are encouraged to ambulate the day of surgery, and are at least to stand at bedside in the first 24 hours. Heparin or Lovenox and sequential compression devices are continued postoperatively for deep venous thrombosis prophylaxis. A modified enhanced recovery after surgery (ERAS) protocol is used for advancing the diet. Alvimopan may be utilized. The nasogastric tube is discontinued immediately after surgery. A Cochrane meta-analysis showed no benefit to leaving a nasogastric tube in place after abdominal surgery [24]. For pain control, reduced use of narcotic medication is encouraged. Xu and colleagues showed significantly reduced occurrence of postoperative ileus and length of hospital stay with use of an ERAS pain management protocol [25]. The protocol calls for nonopioid analgesics including IV acetaminophen being given intraoperatively. Oral acetaminophen, ketorolac, and continuous subfacial infusion of local anesthetic are used postoperatively with narcotic medication for breakthrough pain only. Ileal neobladders are irrigated gently every 8 hours to prevent mucus build-up clogging catheters. The surgical drain is removed on the second postoperative day or when output is low.

Patients are instructed on catheter irrigation prior to discharge. A pouchogram is performed at the time of stent removal four weeks after surgery. If no leak is present, ureteral stents are removed via cystoscopy and the suprapubic tube is removed. The urethral catheter is removed 2–3 days later.

Fluid and electrolyte problems are common after neobladder construction. Hypochloremic metabolic acidosis and hypovolemia are frequently encountered. Goal fluid intake is 2–3 liters of fluid a day. A high-salt diet is needed to replenish sodium losses. Sodium bicarbonate may be prescribed if significant metabolic acidosis occurs. Acid–base and electrolyte disturbances are usually more pronounced with colon reconstruction.

Regimented voiding is important following neobladder formation. Patients are instructed to void every 2–3 hours. Voiding frequency is gradually increased to every 4–5 hours to facilitate an increase in neobladder capacity. Goal neobladder volume is 500 ml. If the patient does not void as frequently as instructed, the neobladder may become overdistended, and a poorly emptying bladder may result. If patients are not able to void or if high post-void residuals are present, clear intermittent catheterization needs to be conducted.

## Outcomes

Multiple series have been published on single and multi-institution experience with RARC with ONB (Table 99.1). Desai and colleagues reported on 132 patients with RARC and ONB at two institutions in the largest series [13]. They found that 47% of patients had a 30-day complication and that 27% of patients had a 30- to 90-day complication; 15.2% of 30-day complications were Clavien-Dindo grade III and higher, and 12.9% of 30- to 90-day complications were grade III and higher. Infectious complications were most common, with sepsis being the most common early complication and urinary tract infection being the most common late complication. Four patients had conversion to an open procedure and were not included in the study. Urine leak was reported in 4.5% of patients, and 7% of patients had a gastrointestinal complication, which included four patients with ileus, two with bowel leak, and two with a neobladder–enteric fistula. The long-term complication rate was low: 2% had reservoir stones, 3.8% of patients had an ureteroileal anastomotic stricture, and less than 1% of patients had a neobladder–vaginal fistula. Mean operative time was 456 minutes. Operative time, hospital

*Source:* Modified from a contemporary review of RARC with intracorporeal ONB [26].

stay, and estimated blood loss improved with surgeon experience.

Complications associated with robot-assisted ONB are similar in nature and frequency to those experienced with the open procedure. Hautmann and colleagues published on 1013 patients undergoing open neobladder creation after radical cystectomy and pelvic lymph node dissection [27]. They reported that 58% of patients experienced at least one complication within 90 days of surgery. Infectious complications were the most common, and 24% of the complications were classified as infectious and 15% were gastrointestinal; 22% of patients experienced a Clavien III–V complication. Notably, 57% of complications were specific to urinary diversion.

The benefits of RARC over open radical cystectomy are not completely defined. In a retrospective review of 100 patients undergoing RARC versus 100 patients undergoing open radical cystectomy from 2006 to 2010, patients in the RARC group had comparable oncologic outcomes with significantly fewer overall and major complications, less estimated blood loss and transfusions, and shorter hospital stay [28]. Mean operative time was approximately 1 hour longer with RARC. Other studies have shown less favorable results for RARC. RARC with extracorporeal urinary diversion was compared to open radical cystectomy in a randomized controlled trial [29]. The RARC group had significantly less intraoperative blood loss but longer operative times. Length of hospital stay and rate of complications were similar. A cost-analysis showed that RARC was more expensive.

The full benefits of minimally invasive surgery may not be realized with an extracorporeal diversion. Potential advantages to a completely intracorporeal procedure were elucidated by the comparison of outcomes of intracorporeal diversion to extracorporeal diversion in patients undergoing RARC in a database by the IRCC [19]. Operative times were similar. Gastrointestinal complications, blood loss, and readmission rate were significantly lower in the intracorporeal group.

There are limited data on health-related quality of life pertaining to intracorporeal urinary diversion. Poch et al. used the Bladder Cancer Index for assessment of bowel, urinary, and sexual domains and the European Organisation for Research and Treatment of Cancer Body Image Scale to measure health-related quality of life outcomes after RARC in 43 patients [30]. In this study, 53% of patients underwent intracorporeal urinary diversion. Five neobladders were created. Patients undergoing intracorporeal diversion had quicker recovery of urinary function than those undergoing extracorporeal diversion. Patients undergoing intracorporeal urinary diversion had lower Body Image Scale (BIS) scores for most postoperative time points, indicating higher patient satisfaction.

Multiple groups have published on functional outcomes after RARC and ONB (see Table 99.1). Daytime continence is excellent while nighttime continence is variable. The majority of patients have good daytime continence. Nighttime continence may be more related to a patient's nighttime voiding habits.

Regarding sexual function, Tyritzis et al. reported on the outcomes of 70 patients who underwent RARC with intracorporeal ONB creation [31]. They reported that 81% of men who underwent a nerve-sparing procedure were potent with or without a phosphodiesterase type 5 (PDE5) inhibitor medication at 12 months following surgery. In the same series, 4 of 6 women evaluated remained sexually active after surgery.

## Keys to success

### Patient positioning

- It is helpful to place the patient in steep Trendelenburg position for performing the RARC and pelvic lymph node dissection.
- Positioning-related injuries can be potentially avoided by placing the patient in a more shallow Tredelenberg position or a supine position and side-docking the robot for creation of the neobladder. The Xi robotic system allows for greater ease with side-docking in the supine position.

### Trocar placement

- All ports are placed at least 2 cm cephalad to the level of the umbilicus.
- The camera port is placed 5 cm cephalad to the umbilicus.
- The robotic fourth arm is placed on the right side.
- Assistant ports are placed on the left side to facilitate stapling bowel and paramedian to aid with suctioning and stapling across the pedicles.

### Bowel isolation

- A premeasured suture can help with measuring out segments of bowel.
- Color-code markings of the bowel (*b*lue for *b*owel segments for future enteric anastomosis and *u*ndyed for *u*rinary conduit) to minimize confusion.
- Vessel loops can be used as markers and handles on the mesentery to reduce direct manipulation of the bowel.
- An indocyanine green arteriogram can be used to delineate bowel vasculature.

### Detubularizing the bowel

- It is helpful to incise bowel over a 24 Fr lubricated chest tube to prevent injury to the posterior bowel wall.

### Posterior plate of the neobladder

- The fourth arm is used to hold traction on the apical stay suture.
- The bowel should be sutured every 15–20 cm with stay sutures for bowel alignment.
- Barbed suture is used for the posterior plate of the neobladder.

### Urethral-neobladder anastomosis

- A Penrose drain can be inserted into the ileal mesentery, and is used as a handle by the fourth robotic arm to provide traction in the direction of the urethral stump.
- The seromuscular layer of the neobladder may be sutured to the rectourethralis muscle with a barbed suture to keep the urethra in close proximity to the neobladder neck for the urethral-neobladder anastomosis.
- A 0° lens is used for the urethral-neobladder anastomosis.

### Uretero-neobladder anastomosis

- A 7.5 cm long suture on a cutting needle is used in a continuous manner.
- Use of 30 cm long ureteral stents aids with their cystoscopic stent removal.

### Closing the neobladder

- Fifty milliliters of sterile saline is injected into the neobladder under direct vision to check for leaks.

## Introduction

In the United States more than 70% of radical prostatectomies are robot assisted using the da Vinci device. In Europe, there is skepticism concerning the spread of robotic systems, based on unfavorable experiences in orthopedics and cost pressures [1]. In Germany and Italy, 25% of radical prostatectomies are performed by laparoscopy. The advantages of this approach include reduced access trauma, less pain and bleeding, and lower transfusion rates [2, 3]. Furthermore, all robot-assisted techniques are based on laparoscopy.

## Historical background

In 1992, Schuessler et al. attempted the first laparoscopic radical prostatectomy (LRP) [4]. However, his technique did not provide any advantages over retropubic radical prostatectomy (RRP) [5]. In 1995, Raboy et al. published a case of extraperitoneal LRP [6]. Richard Gaston (personal communication, 1998) pioneered LRP in 1997, followed by Guillonneau, Vallancien, and Abbou, who popularized the transabdominal access to seminal vesicles [7–10]. In 1999, Rassweiler et al. developed a retrograde technique similar to RRP [11, 12]. In the following years, several groups revisited the French technique [13–16], and in 2000, Bollens et al. revisited the extraperitoneal approach [17].

In 2002, a survey in Germany and Switzerland revealed that 15% of departments performed LRP, but that only 5% did more than 15 cases per year [18]. In 2004, 19.2% of German departments were offering LRP [19]. In 2005, a multicenter study including 5800 patients treated by 50 surgeons was published [20]. In the United States, Gill and colleagues was one of the few groups establishing a program of laparoscopic pelvic surgery [21]. Menon et al. initiated the change when hiring Vallancien and Guillonneau to establish LRP at his institution [22]. Perhaps more importantly, he invested in the da Vinci system and managed to perfect robot-assisted laparoscopic prostatectomy (RALP).

Although RALP has led to a significant decrease in the use of classical LRP within the last decade, particularly in the United States, in Europe, about 25% of all prostatectomies are performed laparoscopically, 35% robot assisted, and 40% still by open technique [23, 24]. Moreover, recent technical improvements including 3D high-definition (HD) or even ultra-HD video-technology, the use of an ergonomic chair, and instruments providing six degrees of freedom have significantly reduced the ergonomic difficulties of the procedure [25–27]. Accordingly, LRP has yielded excellent oncologic outcomes, even in advanced stages [28, 29]. There is still a continuous role for LRP [24, 30] since no study has yet proven any substantial inferiority in oncologic and functional results.

## Indications and contraindications

Indications include men with localized prostate carcinoma and a life expectancy greater than 10 years [30]. All patients with stage less than T3, Gleason score less than 8, and prostate specific antigen (PSA) less than 10 ng/ml are candidates for nerve preservation. Those with suspected extracapsular invasion (T3) or perineural invasion in core biopsies should not undergo nerve-sparing surgery (Table 100.1).

**Table 100.1** Criteria for nerve sparing.

| Clinical stage | |
|---|---|
| T1 | When PSA is relatively low and the number of positive biopsies or the extent of biopsy involvement is limited |
| T2a | A contralateral nerve-sparing procedure can be proposed |
| T2b | A nerve-sparing attempt can result in positive surgical margins and give rise to local failure |

PSA, prostate specific antigen.

Previous transurethral resection of the prostate, abdominal or pelvic surgery, laparoscopic hernia repair, pelvic irradiation, and gross obesity can add to surgery complexity, and such patients should be approached only after considerable experience [28, 31, 32]. Absolute contraindications are abdominal wall infection, generalized peritonitis, bowel obstruction, and uncorrected coagulopathy.

## Anatomy of the prostate

Despite early descriptions by Walsh et al. and a recent consensus paper by Walz et al. [33–35], there is still no consensus on the nomenclature of all described anatomical structures. Therefore recently, the European Association of Urology (EAU) Section of Uro-Technology (ESUT) proposed a uniform nomenclature [36].

### Different types of nomenclature and terminology

In general terms, descriptions/nomenclatures are either surgical, anatomical, or eponymical, but some authors use different terminologies (Table 100.2). The anatomical description is defined according to the Federative Committee on Anatomical Terminology's *Terminologia Anatomia, International Anatomical Terminology* published in 1998 [37]. Usually, surgeons describe their technique based on the "surgical terminology," using

**Table 100.2** Summary of existing anatomical descriptions of relevant anatomy during radical prostatectomy.

| Anatomical structure (surgical nomenclature) | Anatomical description (anatomical nomenclature) | Eponymical description | Other description(s) |
|---|---|---|---|
| Pelvic fascia | Fascia pelvis parietalis | Endopelvic fascia | – |
| Levator fascia | Fascia levatoris | Outer layer of Walsh's lateral pelvic fascia | Periprostatic fascia<br>Parapelvic fascia |
| Prostatic fascia | Fascia prostatica | Inner layer of Walsh's lateral pelvic fascia | |
| Posterior prostate visceral fascia | Septum rectovesicale | Denonvillers' fascia | Prostato-seminal vesicular fascia<br>Posterior prostatic and seminal vesicle fascia |
| Vesico-prostatic muscle | Musculus vesico-prostaticus | | Anterior layer of Denonvillers' fascia<br>Posterior longitudinal fascia |
| Rectal fascia | Fascia propria rectalis | Outer leaf/posterior layer of Denonvillers' fascia | |
| Dorsal vein plexus | Plexus venosus dorsalis penis | Santorini's plexus | Dorsal vascular complex |
| Puboprostatic ligaments | Ligamenta puboprostatica | | Pubovesical ligaments |
| Anterior prostate visceral fascia | Visceral endopelvic fascia | | Anterior periprostatic fascia (covering detrusor apron and McNeal's anterior fibromuscular stroma) |
| Fascial tendinous arch of plevis | Arcus tendineus fasciae pelvis | | Puboprostatic collar (plus puboprostatic ligaments) |
| Puboperineal portion of levator ani | Musculus levator urethrae (hiatus urogenitalis) | Quick stop muscle of Gosling | Puboperinealis muscle |
| Rhabdo-sphincter of urethra | Sphincter urethrae externus | | Striated urethral sphincter |
| Lisso-sphincter of urethra | Sphincter urethra internus | | Intrinsic sphincter |
| Ischioprostatic ligaments | | Walsh's pillars | |
| Posterior raphe | Musculus anoperinealis | | Rectourethralis muscle |

Modified from Rassweiler et al. [36].

terms translated from Latin. One example would be the term “endopelvic fascia” instead of “fascia pelvis parietalis.” Eponymical descriptions are based on the name of the first surgeon or anatomist publishing an article on the relevant anatomical structure, such as the “plexus Santorini” or “Denonvilliers’ fascia” [38, 39]. In addition to this, some authors use different terms to describe important structures, such as the “paraprostatic or periprostatic fascia” instead of “levator fascia” or “fascia levatoris ani” [40].

## Periprostatic fascial anatomy

Walsh et al. described three layers covering the anterolateral surface of the prostate [33, 34]: the prostatic fascia overlaying the prostatic capsule and levator fascia (fascia diaphragmatica pelvis superior). Both fasciae fuse laterally to form the lateral pelvic fascia covered by the endopelvic fascia (fascia pelvis parietalis) reflecting off the transversalis fascia (Figure 100.1). This area is also described as the tendinous arch of the pelvis. Posteriorly, there are two layers: Denonvilliers’ fascia (prostatoseminal-vesicular fascia; septum retrovesicale) and the prostatic capsule. The neurovascular bundles run along the posterolateral part of the prostate between levator and prostatic fascia and contain branches from the inferior vesical arteries running medial to cavernosal nerve branches originating from the pelvic plexus. These vessels enter the capsule through the prostatic fascia. Some authors describe the levator fascia also as the periprostatic or parapelvic fascia [40].

## Course and branches of pudendal nerve

For preservation of continence, the course of intrapelvic branches of the pudendal nerve is more relevant than the course of neurovascular bundless [41]. N. pudendus has three branches: (i) nervi rectales inferiors, (ii) nervi perinealis, and (iii) nervus dorsalis penis. The perineal rami support the penile muscles (m. bulbospongiosus, m. ischiorectalis, m. ischiocavernosus) and the striated urethral sphincter. Lesions of perineal branches lead to incontinence. A., V. and N. pudendus enter the small pelvis through the foramen ischiadicus minus, then follow the canalis pudendalis (Alcock’s canal). Finally the nerve divides medially into its three branches. The perineal rami supporting the striated urethral sphincter run underneath the levator fascia (fascia diaphragmatica pelvis superior).

## Anatomy of urethral sphincter apparatus and the bladder neck

The urethral sphincter apparatus consists of the horseshoe-shaped rhabdosphincter and smooth-muscle longitudinal and circumferential lissosphincters [35]. In addition, the prostate is connected laterally to the urethra by thickened

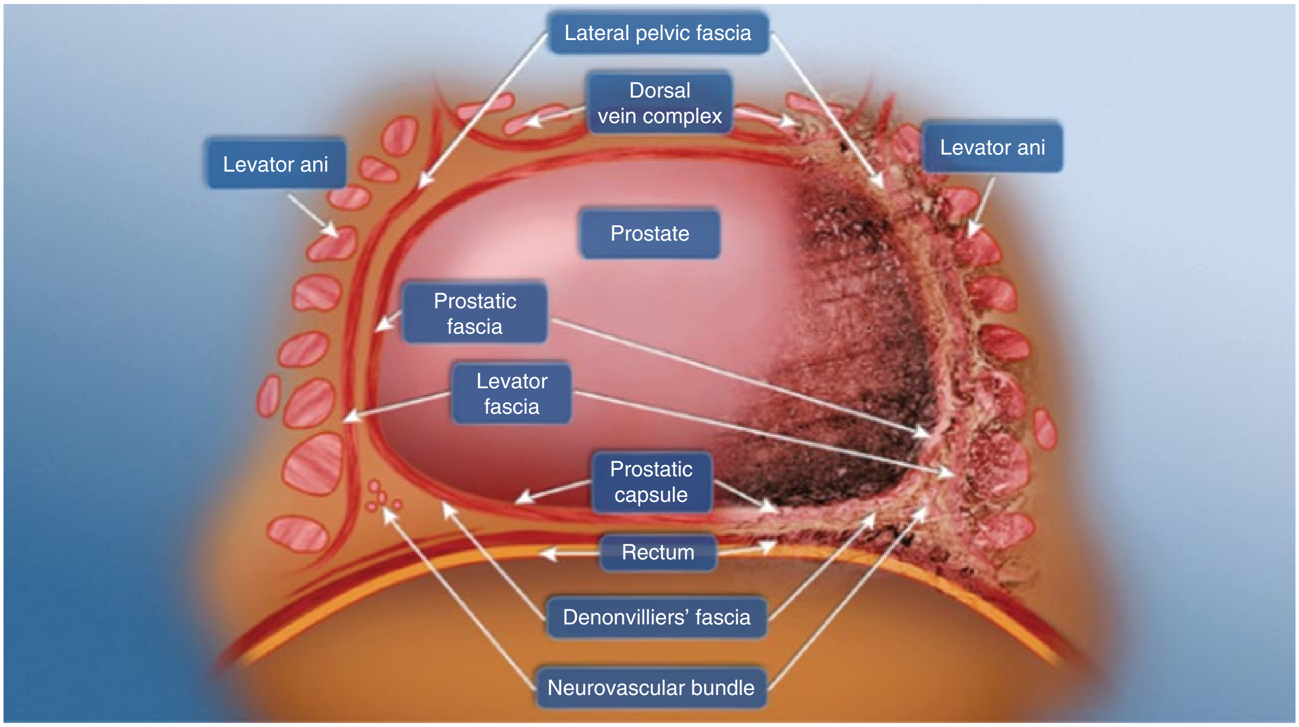

**Figure 100.1** Anatomical basis of the prostate: fascial anatomy of the prostate according to Walsh et al. [33].

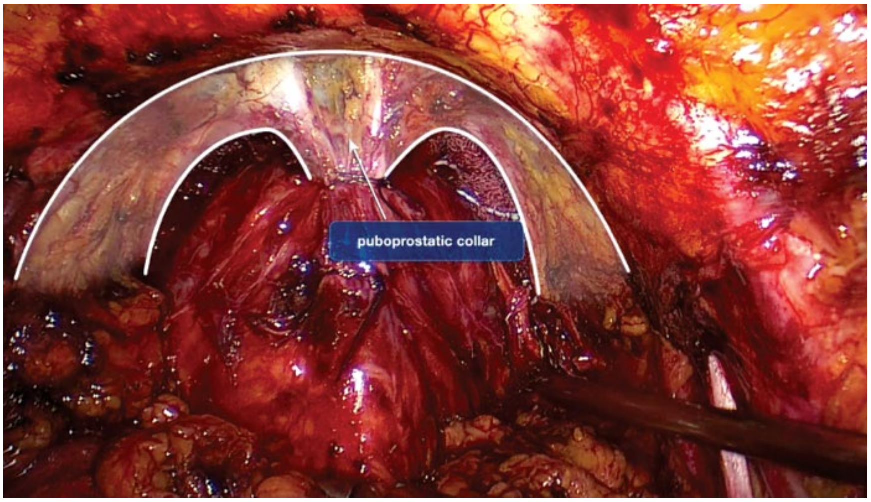

**Figure 100.2** Concept of preservation of puboprostatic collar according to Takaneda et al. [58].

fascial band components (Walsh's pillars, Müller's ischioprostatic ligaments). Anteriorly, puboprostatic (pubovesical) ligaments suspend the urethra. For preservation of the puboprostatic collar it is important to keep this part completely intact (Figure 100.2). Posteriorly, the sphincter apparatus is supported by the median fibrous raphe and rectourethralis muscle. In addition, the striated sphincter is flanked by thickened anteriomedial edges of the anterior levator ani muscle (i.e. urogenital hiatus), forming an incomplete sling behind the urethra. On contraction they forcefully propel the prostate and prostatourethral junction upward and forward, enabling quick cessation of urination.

The precise anatomy of the bladder neck and its effect on continence is still unclear. In the transverse plane, the bladder neck is composed of two different muscles, the ventrolateral and dorsal longitudinal muscles, which are positioned in an oblique direction. When the bladder neck is examined in a truly transverse direction, there is a distinct circular muscle called the musculus sphincter vesicae, possibly representing the rationale for bladder neck preservation [36].

### Neurologic aspects of urinary continence mechanism

Both somatic pudendal nerve and autonomic branches of the pelvic plexus are involved in the urinary continence mechanism. Somatic motor innervation passes from the anterior horn of S2–4 segments and travels to the external sphincter via an intra- and an extrapelvic branch of the pudendal nerve. Additional intrapelvic extrapudendal nerve fibers from S2–3 pass lateral to the pelvic plexus and then continue along the dorsolateral surface of the rectum, until they disappear into the levator ani muscle and terminate in the urethral sphincter [40]. In addition to the efferent autonomic and somatic nerve fibers innervating the sphincteric musculature, intrapelvic afferents from the membranous urethra contribute to urinary continence. Intact afferents lead to a conscious sensation of urine entering the membranous urethra, inducing either a spinal reflex or voluntary contraction of the rhabdosphincter. These afferent fibers run in branches of the pelvic plexus and the intrapelvic branch of the pudendal nerve.

## Operative techniques

Four approaches have been described: (i) transperitoneal descending with initial dissection of the seminal vesicles [8]; (ii) transperitoneal ascending [12]; (iii) extraperitoneal descending [42, 43]; and (iv) extraperitoneal ascending [44].

### Patient positioning and trocar arrangement

The patient lies in lithotomy position. A rectal balloon catheter is inflated with 40–60 ml of air. The operating table is placed in a 15–20° Trendelenburg (Figure 100.3a). A 16 Fr Foley catheter is inserted. Some authors prefer an incline of up to 30–40° [7]. A semi-lunar or W-shaped arrangement of 5 and 10 mm trocars is recommended (Figure 100.3b,c).

### Access to the prostate

Transperitoneal access is accomplished with a Veress needle (maximum pressure 15 mmHg). The peritoneum is incised over both seminal vesicles and the vas deferens are exposed and divided. Thereafter, the space of Retzius is developed by transection of the urachus after filling the bladder with 200 ml of saline.

Extraperitoneal access uses a periumbilical incision followed by extraperitoneal blunt dissection of the space of Retzius (balloon trocar; Figure 100.4). The other

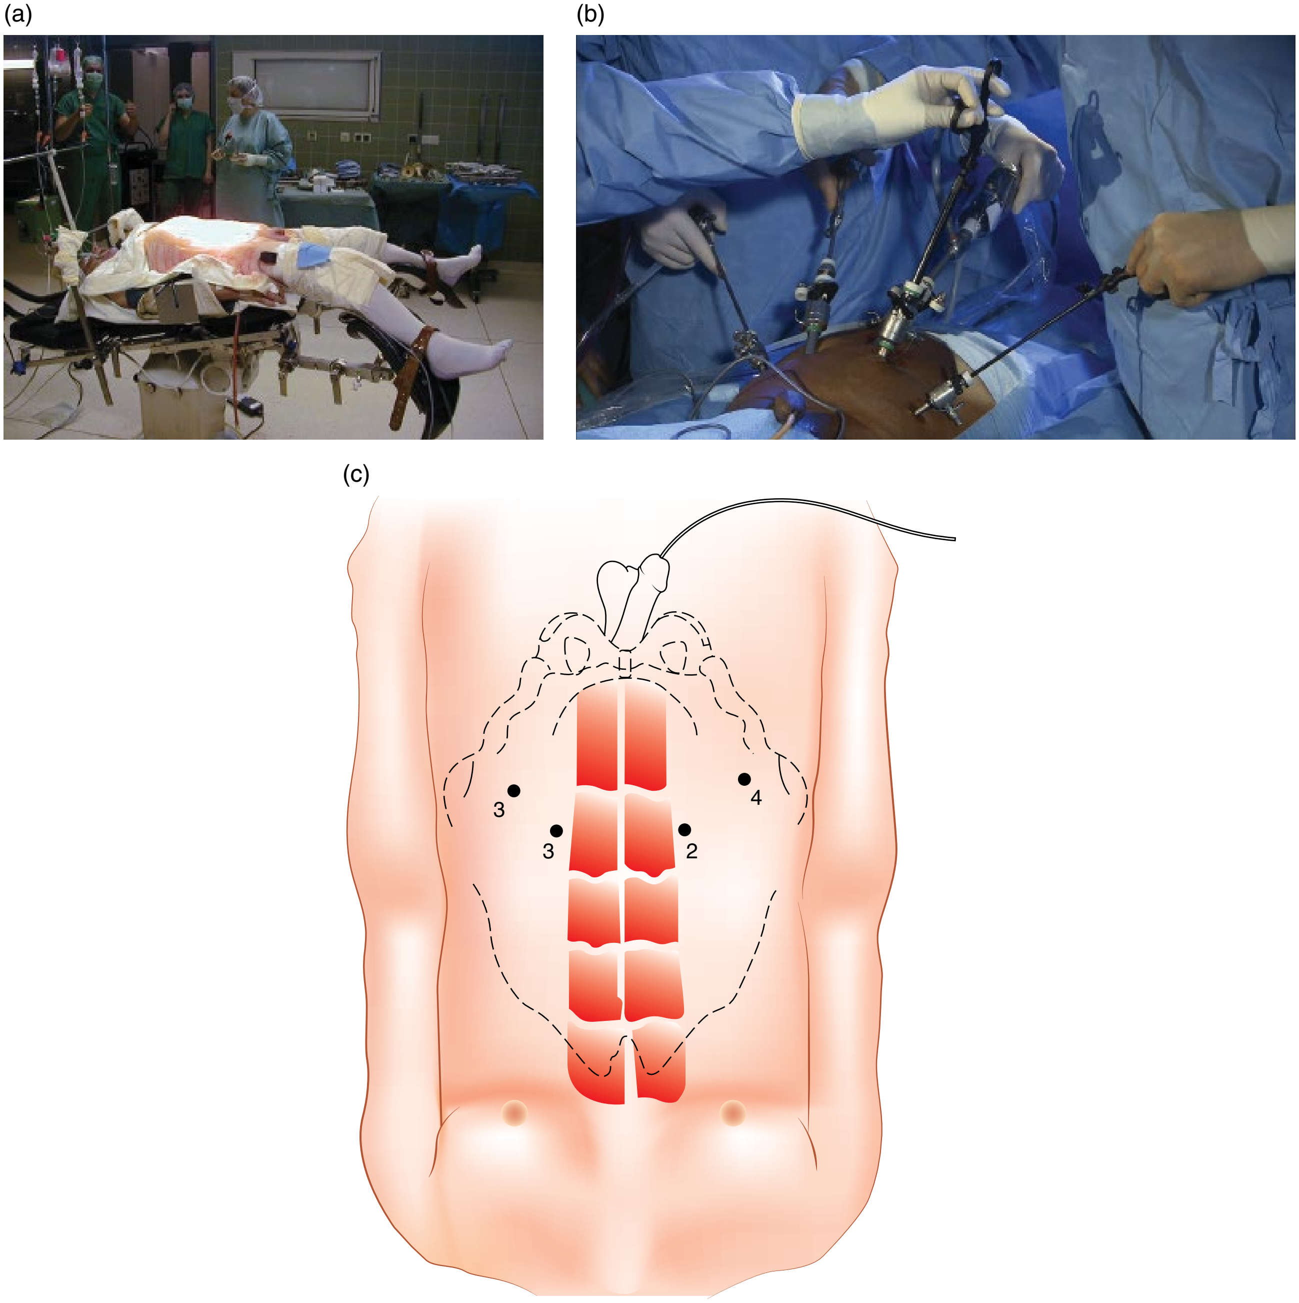

**Figure 100.3** Positioning of the patient and trocar arrangement for laparoscopic radical prostatectomy. (a) Lithotomy position. (b) Classic supine with adducted legs and 15–20° Trendelenburg and W-shape arrangement (Heilbronn technique). (c) Semilunar arrangement according to Ukimura et al. [21].

ports are placed after establishing the pneumo-extraperitoneum (maximum 12 mmHg).

### Extraperitoneal versus transperitoneal approach (Table 100.3)

Transferability of the transperitoneal access was demonstrated [10–14, 45–48]; however, the extraperitoneal descending technique is easier to learn, as reflected in the shorter operating times [20, 31, 42]. Eliminating the transperitoneal dissection of seminal vesicles may shorten operative time by 50 minutes [49]. Comparable surgical results between extraperitoneal and transperitoneal LRP have been published [20, 50–54]; some authors emphasize the advantages of the extraperitoneal approach (i.e. no bowel lesions, ileus, and peritonitis) [44, 49], whereas others found no differences [53, 54].

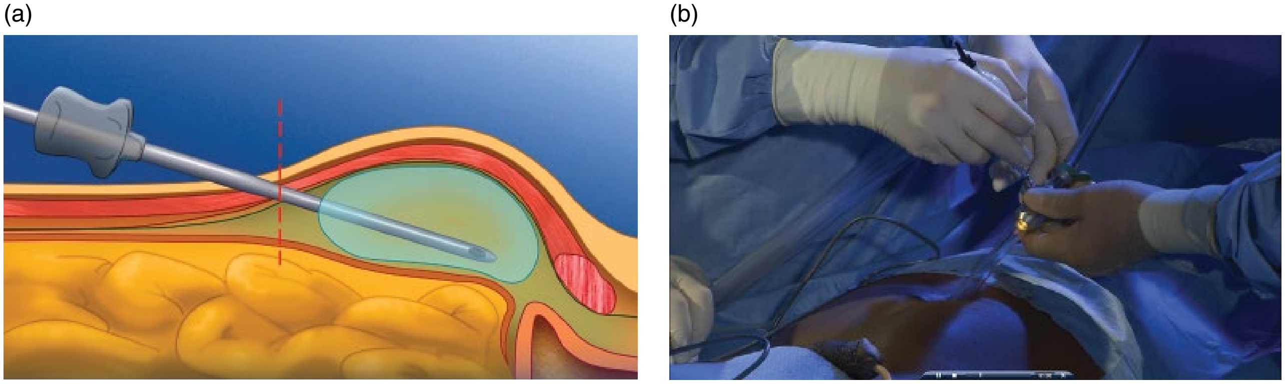

**Figure 100.4** Balloon dissection of the space of Retzius under endoscopic control. (a) Schematic view. (b) Introduction of the telescope via the balloon trocar.

**Table 100.3** Advantage and disadvantage of extraperitoneal versus transperitoneal laparoscopic radical prostatectomy.

| Advantages extraperitoneal | No advantage one technique over the other | Advantages transperitoneal |
|---|---|---|
| No contact with bowel<br>Previous abdominal surgery<br>Fewer problems with urine extravasation<br>Gross obesity<br>Simultaneous inguinal hernia repair | Operating time<br>Morbidity<br>Complication rate<br>Positive surgical margin<br>Continence | Larger room<br>Less tension on anastomosis<br>Minimal risk of lymphocele in case of extended lymph node dissection |

## Routes of dissection

The antegrade technique starts at the bladder neck. The Foley catheter is used as a retractor to expose and cut the posterior wall of the bladder neck (Figure 100.5a). Subsequently, the vesicoprostaticus muscle is divided, exposing the vas deferens and seminal vesicles. Using the vas as a retractor, Denonvilliers' fascia is incised to dissect the posterior surface of the prostate. Proximal pedicles are clipped and divided (Figure 100.5b). Following apical dissection the dorsal vein complex (DVC) is sutured and divided. Finally, the urethra is transected (Figure 100.5c).

The retrograde technique starts at the apex with suturing and dividing of the DVC. Thereafter, the urethra is incised (Figure 100.6a). The Foley catheter is used as a retractor during prostatic posterior dissection (Figure 100.6b). Subsequently, it serves as a retractor to expose the bladder neck, which is incised to reach the vas and seminal vesicles and to control the proximal pedicles (Figure 100.6c).

### Retrograde versus antegrade technique

Although the retrograde technique is more popular in open surgery [45, 55–57], laparoscopic and robotic surgeons favor the antegrade approach [15, 22]. The early control of prostatic pedicles and late division of the DVC ensure minimal bleeding.

## Technical aspects for early continence

Long-term continence exceeds 90% in most laparoscopic and robotic series; however, initially early continence (i.e. at three months) used to be still in the range of 40–50% [3]. Several strategies have been proposed [40, 58–65]:

- preservation/reconstruction of the puboprostatic ligaments;
- suspension of the DVC;
- dissection of a long urethral stump;
- preservation of the bladder neck;
- preservation and reconstruction of the rectourethralis muscle.

Recently, Takenaka et al. [58] introduced the strategy of preservation of the puboprostatic collar. We have added the preservation of the levator fascia to this strategy, yielding excellent short-term continence results.

### Heilbronn technique for early continence (see Videos 100.1 and 100.2)

#### *Conventional technique*

Following lateral incision of the endopelvic fascia, the levator fascia is perforated, creating a dissection plane along the levator ani muscle (Figure 100.7). The levator ("periprostatic") fascia is incised secondarily to perform an interfascial nerve-sparing technique [66–69]. This

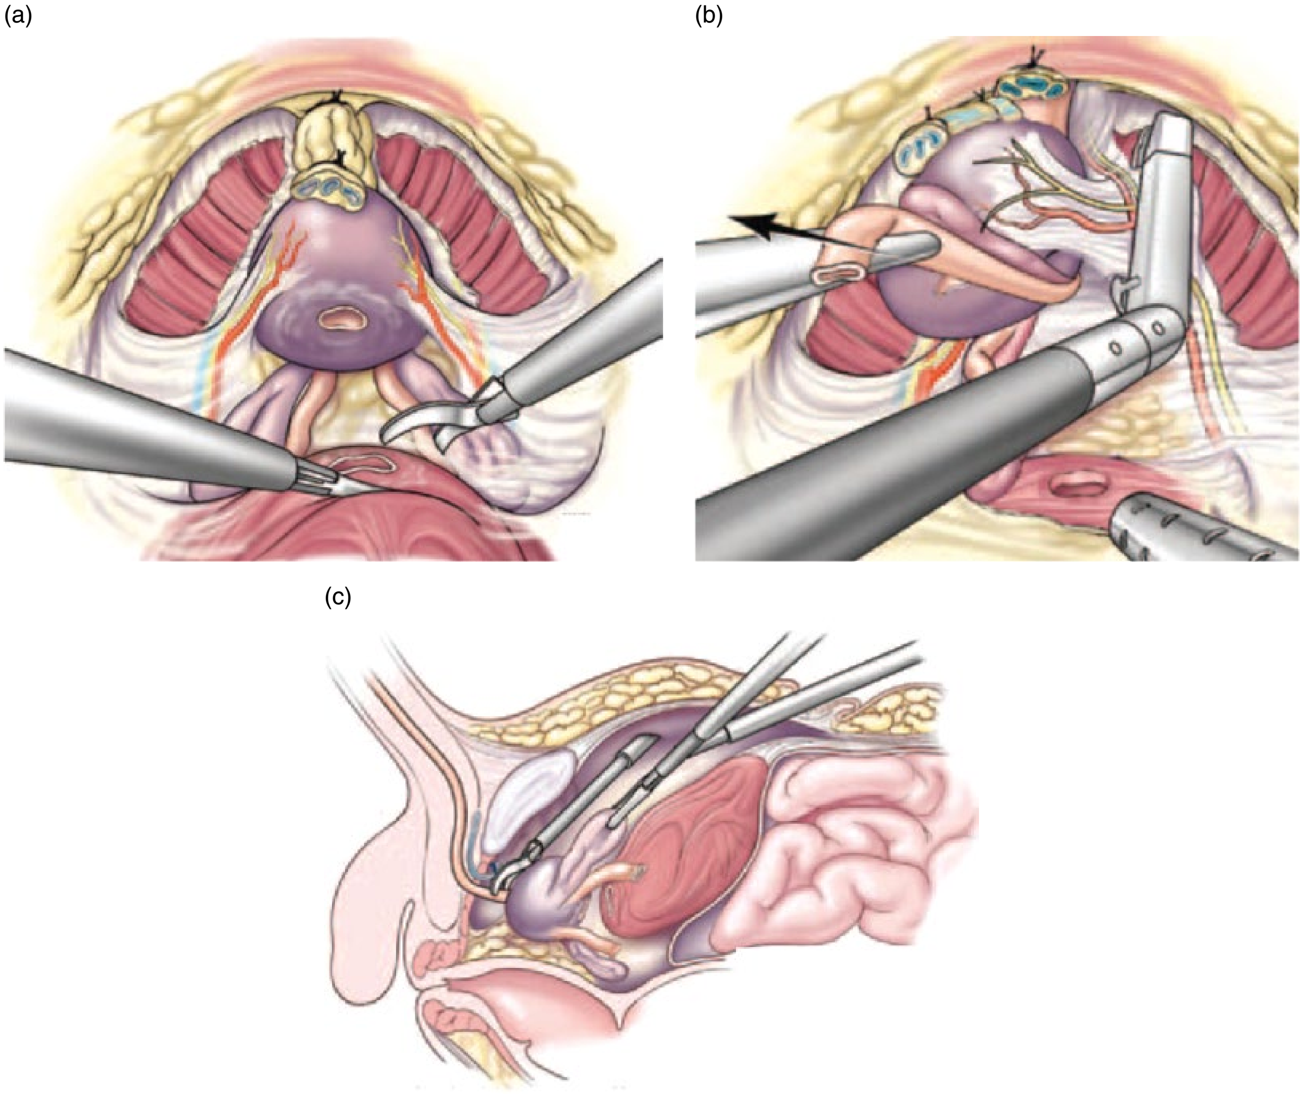

**Figure 100.5** Antegrade technique of laparoscopic radical prostatectomy according to Ukimura et al. [21]. (a) Opening of the bladder neck and dissection of the vas deferens and seminal vesicles. (b) Dissection of the posterior surface and control of prostatic pedicles using the vas deferens as a retractor. (c) Division of the urethra.

approach also includes division of both puboprostatic ligaments and distal ligation of the DVC (Figure 100.8).

#### *Preservation of levator fascia and puboprostatic collar*

Following medial incision of the endopelvic fascia below the puboprostatic ligaments, the avascular plane between the levator and prostatic fascia is developed (Figure 100.7). Thus, the intrapelvic branch of the pudendal nerve remains covered by levator fascia. The DVC is sutured over the mid part of the prostate to preserve the puboprostatic collar. For division of the DVC a 120° endodissector is placed over the prostatovesical junction (Figure 100.8), rotating the prostate towards the urethra, and the anterior striated sphincteric complex is reached. The urethra is transected just distal to the verumontanum, preserving the rectourethralis muscle. Whenever indicated, we perform a bladder neck-sparing technique. After dividing the bladder neck, the prostatovesicle muscle is incised close to the prostate to be used for posterior reconstruction of the anastomosis.

#### Non-nerve-sparing technique

If nerve sparing is contraindicated, the neurovascular bundles are clipped distal to the urethra using 10 mm titanium clips. No Hem-o-lok clips are used to avoid migration into the anastomosis. The proximal pedicles are clipped pararectally to minimize the risk of positive margins.

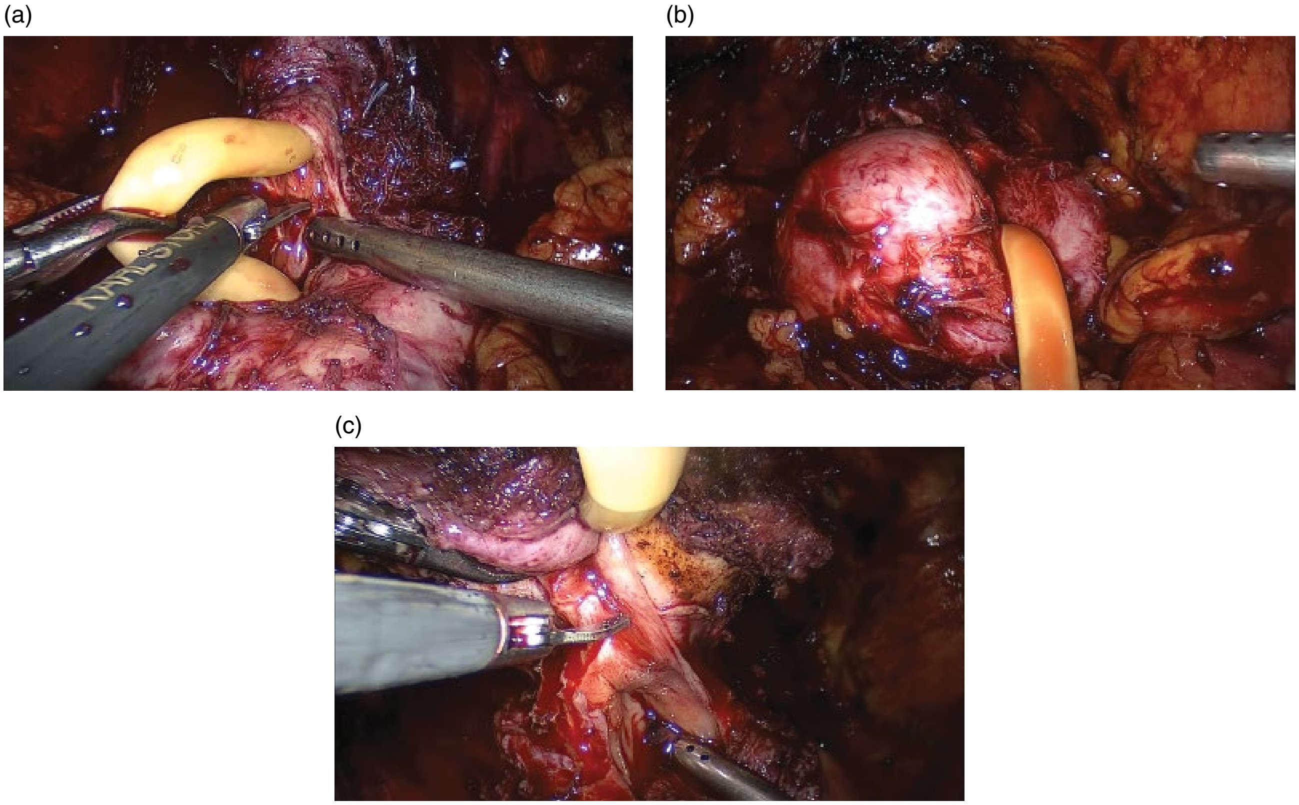

**Figure 100.6** Retrograde technique of laparoscopic radical prostatectomy (Heilbronn technique). (a) Division of the urethra. (b) Posterior dissection using the Foley catheter as a retractor. (c) Bladder neck incision using the loop of the catheter as a retractor.

### Nerve-sparing techniques

Preservation of the neurovascular bundles can be performed using an antegrade or retrograde technique [69–71].

#### *Antegrade technique*

Antegrade dissection starts with the division of the proximal pedicle and release of the neurovascular bundles at the base of the prostate [8]. Finally, the bundles can be separated bluntly from the apex. The neurovascular bundles cannot easily be visualized without initially incising the levator fascia and developing the lateral neurovascular bundle groove [69]. Gill et al. proposed intraoperative transrectal ultrasound monitoring to identify the course of the neurovascular bundle [66]. Interfascial neurovascular bundle dissection uses the prostatic fascia as a visible landmark, starting with its separation lateromedially [31, 69].

#### *Retrograde technique*

Retrograde dissection reproduces the open technique with earlier release of the neurovascular bundles [70–72]. The space between the urethra and the neurovascular bundles is dissected bluntly until Denonvilliers' fascia can be identified. The rectal balloon is inflated with 40–60 ml of air. The prostatic fascia is incised and small branches to the neurovascular bundles are controlled with 5 mm titanium clips (Figure 100.9a). The same is achieved during posterior dissection after incision of the urethra. Following division of the bladder neck, the course of the neurovascular bundles is visualized to exactly determine the clip position to control the proximal pedicle (Figure 100.9b).

#### *Antegrade versus retrograde nerve sparing (Table 100.4)*

All steps can be performed using either technique, and in the meantime hybrid techniques using steps of both approaches have been described [73]. Commonality exists with regard to accomplishing an interfascial dissection and early visualization of the neurovascular bundles, use of task-specific instrumentation such as fine right-angled and curved dissectors, and avoiding thermal energy during steps relevant to neurovascular bundle preservation [69, 71, 74].

### Entrapment of the specimen

The specimen is entrapped in the self-opening extraction bag (Karl Storz, Tuttlingen, Germany) by pulling the purse-string out onto the skin surface via the left 10 mm port. Thereafter, the port is reinserted parallel to the bag.

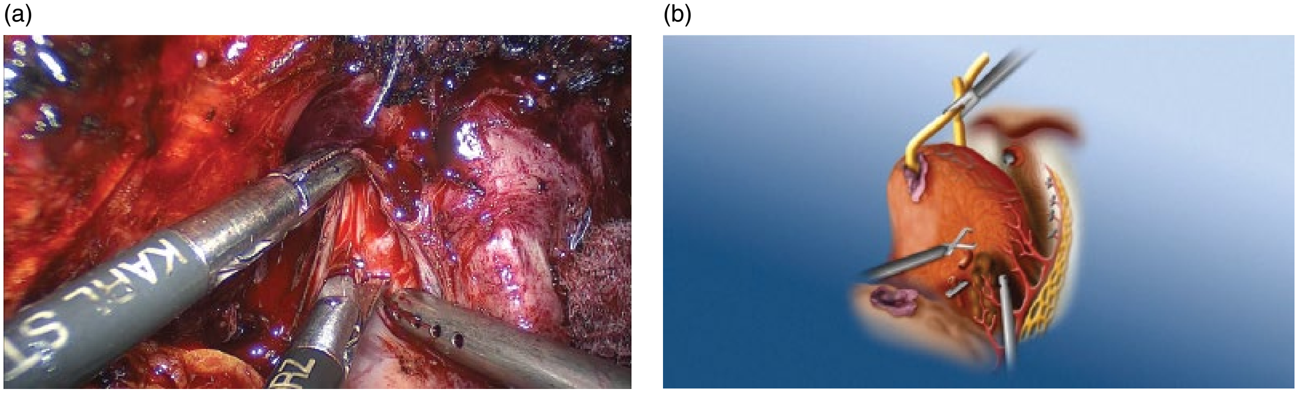

**Figure 100.9** Retrograde nerve-sparing technique. (a) Early release of the neurovascular bundles at the apex using 5 mm titanium clips. (b) Controlled division of the proximal pedicle.

## Urethrovesical anastomosis

For the urethrovesical anastomosis, the right medial port and left lateral port are used to provide an optimal angle (25–35°) between the instruments (Figure 100.10a). The anastomosis can be accomplished by the interrupted, continuous, or single-knot technique [64].

### Posterior reconstruction

Rocco and Rocco reported significant improvement of early continence following adaptation of the prostatovesicle muscle to the rectourethralis muscle [65] (Figure 100.10a–c). However, Menon et al. did not find any advantage over a single-knot technique alone [75]. Using the described technique, Rocco suture did not improve early continence. However, it did release tension on the anastomosis as well as the neurovascular bundles.

### Van Velthoven single-knot technique (see Video 100.1)

Anastomosis is performed using two bicolored sutures (17 cm PDS 3-0 and Biosyn; RB1-needle) knotted together [76, 77]. At this stage it is important that the assistant pushes the perineum with the urethral stump towards the surgeon ("perineal push"). We start at the 6 o'clock position on the bladder neck, subsequently taking the posterior urethra. Once the posterior part of the anastomosis is accomplished, the sutures are pulled to adapt the bladder neck and urethra (winch mechanism) (Figure 100.10d–f). An 18 Fr catheter is inserted and the anastomosis is completed. In difficult situations, a special bougie allows insertion of a guidewire for safe placement of the catheter.

### Reconstruction of the bladder neck

Posterior bladder neck reconstruction is necessary when the orifices are close (<5 mm) to the resection line (i.e. in cases of a large mid lobe). Anterior reconstruction may become necessary when bladder neck preservation is not possible or indicated.

### Anterior reconstruction

Based on anatomical studies Tewari et al. promoted the anterior reconstruction of the dorsal vein plexus and the reattachment of the arcus tendineus and puboprostatic

**Table 100.4** Advantages and disadvantages of retrograde versus antegrade neurovascular bundle preservation during laparoscopic radical prostatectomy.

| Technique | Advantages | Disadvantages |
|---|---|---|
| Retrograde | Earlier identification of neurovascular bundles (NVB) (i.e. hemostasis at dorsal vein plexus)<br>Exposure of NVB during every step<br>Direct transfer of existing techniques of open radical prostatectomy | Technical difficulty<br>Late control of proximal pedicle |
| Antegrade | Early control of prostatic pedicle, resulting in minimal bleeding<br>Early control of seminal vesicle arteries<br>Better working angle for the instruments<br>Dissection proceeds along surgeon's natural line of site | Later identification of NVB still covered by levator fascia (compensated by early incision of endopelvic fascia)<br>Suboptimal exposure of prostatic base during control of prostatic pedicles |

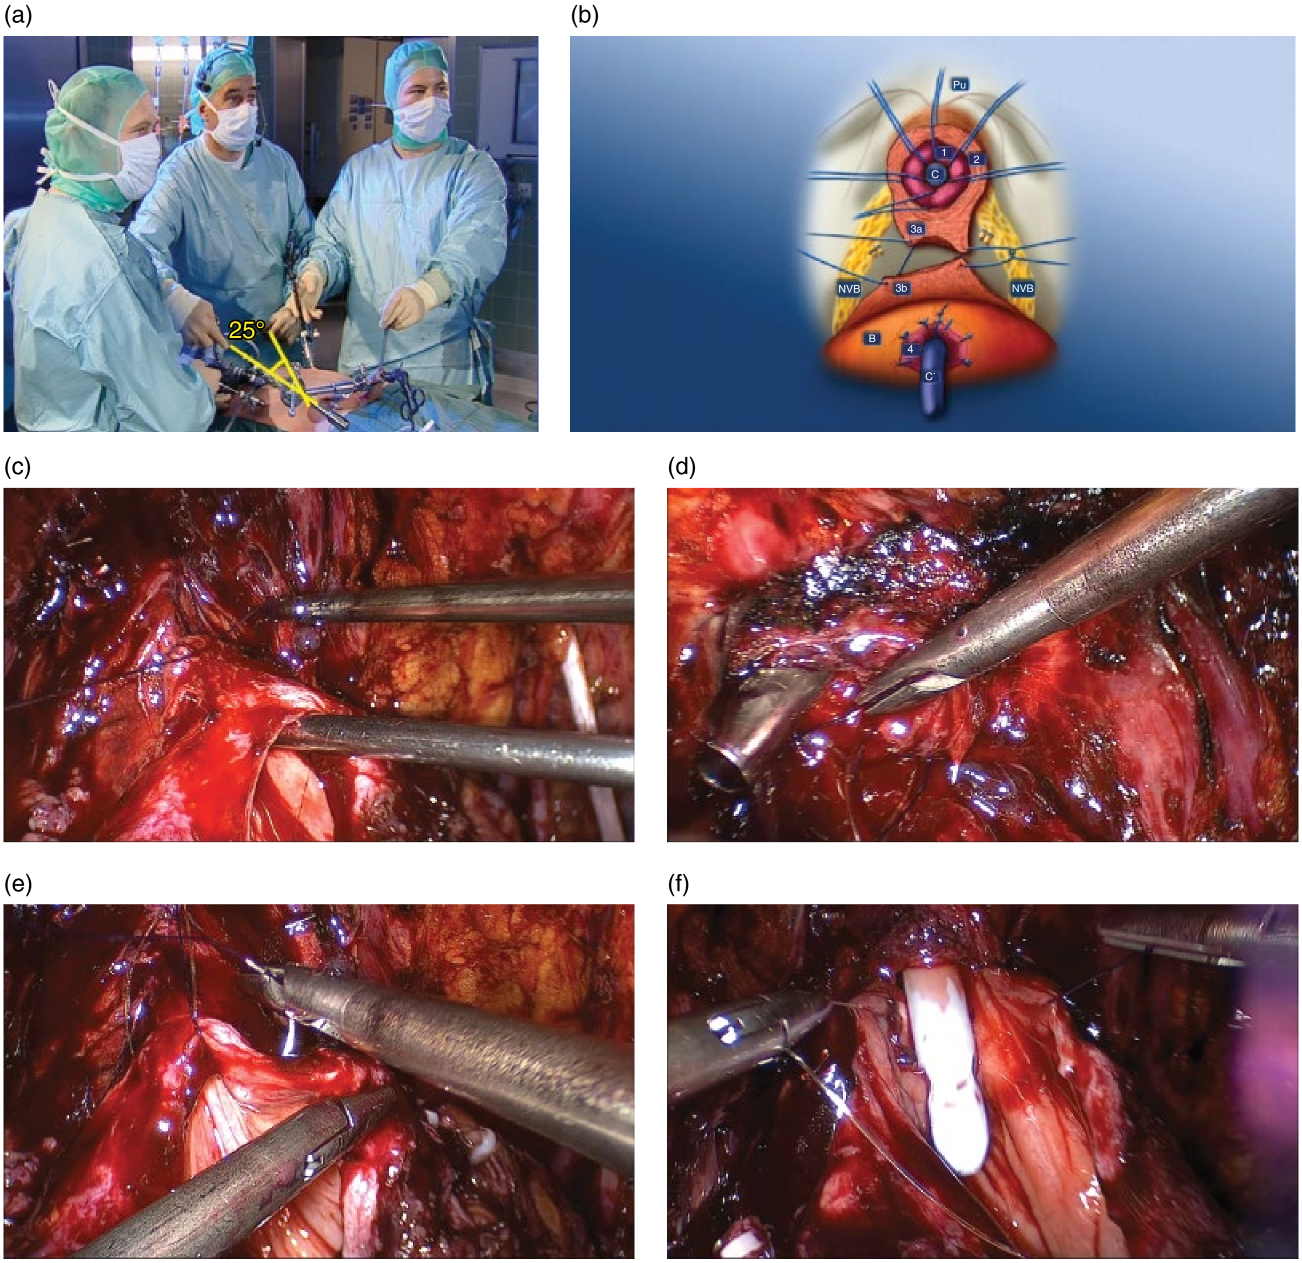

**Figure 100.10** Urethrovesical anastomosis. (a) Suturing using the right medial port for the needle driver to achieve an appropriate angle between the instruments. (b) Schematic posterior reconstruction according to Rocco and Rocco [65], with adaptation of the vesicoprostatic muscle to the rectourethralis muscle and posterior plate. B, bladder; NVB, neurovascular bundles; C, catheter; Pu, periurethral plate (prostate-vesical muscle and central raphe); 1–4, position of stitches. (c) Rocco stitch. (d) Single-knot technique according to van Velthoven using a bicolored suture. Urethral stitch (inside–outside). (e) Bladder neck stitch (outside–inside) at 4 o'clock. (f) Adaptation of the posterior part of the anastomosis using the winch principle.

plate to the bladder neck [78]. Even if other authors could not confirm its positive effect on early continence [75], the concept of total reconstruction of the urethrovesical junction seems to be an appealing concept. Early continence may depend more on other factors, such as preservation of the levator fascia minimizing the trauma to the branches of the pudendal nerve, but total reconstruction of the urethrovesical junction has a significant impact on the healing process of the anastomosis.

## Retrieval of the specimen

After placing the drainage tube via the right medial 10 mm port, the bag is extracted via the periumbilical incision.

## Results

A systematic literature search using the terms "laparoscopic radical prostatectomy," "ergonomics," "comparative studies," and "robot-assisted radical prostatectomy" was performed in Medline, Embase, and Pubmed. Inclusion criteria were randomized controlled trials (RCT) or observational series and reviews of good quality. Primary outcome parameters focused on the impact of ergonomics on performance and learning curve of the different techniques. Secondary outcome parameters were functional and oncologic outcomes after radical prostatectomy. In Heilbronn, we have performed 3505 LRPs since March 1999, including 869 with da Vinci.

Twenty-seven comparative studies were identified: 23 compared LRP with RRP and 4 compared LRP with RALP: one randomized controlled trial [79]; 12 nonrandomized prospective studies [45, 54, 80–101]; seven retrospective studies compared to contemporary series [91–96]; and four retrospective studies using historical series as controls [97–100]. Furthermore, there are robust long-term data from major centers as well as from recent meta-analyses [2, 3, 56, 101–104]. Based on this, there is an increasing body of evidence that laparoscopic and robot-assisted radical prostatectomy provide advantages with respect to surgical complications such as risk of transfusion and postoperative pain without deterioration of oncologic and functional outcomes [105, 106].

## Perioperative data

Comparison of early laparoscopic series to relevant contemporary series of RRP [8, 54, 56, 81, 86, 87, 92, 93] includes a major bias related to the different levels of surgical experience. Based on today's training programs, about 50 cases are necessary to learn LRP [47, 50].

### Operating times

Increased operating times (180–330 minutes) was one of the criticisms leveled against LRP (compared to RRP, 105–197 minutes; Table 100.5A). However, Frede et al. showed a decrease in operative time from 332 minutes for the first 50 cases to 196 minutes for the last 50 cases after 1000 procedure [47]. Similar decrease in operating time was seen with the extraperitoneal approach [107, 108]. Nowadays, at experienced centers mean duration of the operation ranges between 150 and 200 minutes.

### Blood loss and transfusion rates

Compared to RRP, LRP demonstrated a significantly lower blood loss (189–1100 ml vs. 550–1550 ml) and transfusion rate in cumulative analysis (Table 100.5B). In one study comparing 1134 LRP versus 3458 RRP cases, the transfusion rate was 4% versus 55% [109]. The study by Hu also revealed a 20% transfusion rate for RRP versus 4% for minimally invasive techniques [110].

### Postoperative pain

Most of the studies used a visual analog scale or the morphine equivalent requirement [3]. Pain scores were slightly lower during postoperative day 1 in patients undergoing LRP [79]. There was no statistically significant difference in the required morphine sulfate equivalent. The level of postoperative pain might be affected by epidural infusion of analgesic following RRP [109].

### Catheter times and hospital stay

Overall, catheterization times ranged between 6 and 14 days after LRP and 5 and 22 days after RRP [45, 54, 80–90]. The catheter was withdrawn early in a higher percentage of LRP patients compared to RRP. Length of stay in hospital was significantly shorter for LRP patients [45, 54, 80–96]. However, there is a wide variation in length of stay due to the differences in economic health systems and cultural background.

## Complications

We classified complications according to the modified Clavien system [111] (Table 100.6). In a study with follow-up of 37 months, Rabbani et al. reported 19.9% Clavien I–II complications following RRP compared to 37.3% after LRP [109]. However, they listed transfusion rates of 55% after RRP and 4% after LRP separately. Therefore, many patients receiving transfusions were not registered as Clavien II. Novara et al. observed 19% Clavien I–II (including 5.3% transfusions), similar to the rates in our series (21.7% including 10.4% transfusions) [3, 109, 112]. In Rabbani et al.'s series, Clavien III–V complications occurred in 6.4% after RRP and 8.9% after LRP, compared to 11.4% in our series (Table 100.6).

The low conversion rates (1.9–2.2%) in all major series reflect the careful introduction of LRP [20, 79]. In a multicenter study, technical reasons or unclear anatomy of the tumor were the reasons for conversion to open surgery [113]. A single retrospective study reported a lower rate of anastomotic strictures in LRP compared to RRP [93]. No differences were found between LRP and RALP [102, 103, 114].

### Predictive factors for complications (Table 100.7)

Novara et al. identified prostate volume greater than 50 cm as an independent predictor of complications [114], but Zorn et al. did not find any impact of prostate

[a] Clavien I: any deviation from the normal intraoperative or postoperative course, including the need for pharmacologic treatment other than antiemetics, antipyretics, analgesics, diuretics, electrolytes, or physiotherapy; Clavien II: complications needing only the use of intravenous medications, total intravenous nutrition, or blood transfusion; Clavien IIIa: complications needing surgical, endoscopic, or radiologic intervention under local anesthesia; Clavien IIIb: complications needing surgical, endoscopic, or radiologic intervention under general anesthesia; Clavien IVa: life-threatening complications requiring intensive care unit (ICU) management: single organ dysfunction; Clavien IVb: life-threatening complications requiring ICU management: multiorgan dysfunction; Clavien V: death of the patient.

volume for RALP [115]. In addition, operating time longer than 4 hours, non-nerve-sparing technique, and transperitoneal access predicted a higher rate of complications. However, there is a relationship between the institutional learning curve and these factors, with the number of cases performed by the surgeon being a predictive factor [115].

## Oncologic results

### Positive margins

Comparative and cumulative studies have provided data of positive surgical margin (PSM) rates ranging from 11% to 37% after RRP, 11–30% after LRP, and 9.6–26% after RALP (Table 100.8). Guazzoni et al. demonstrated overlapping PSM rates [79]. No differences were

found between LRP and RALP, considering early and more advanced phases of the RALP learning curves [102, 116, 117].

### Prostate specific antigen recurrence

There are still only few long-term studies [118–122]. Guillonneau et al. reported an overall actuarial biochemical progression-free survival rate of 90.5% at 3 years [118–120]. The rates were 92% for pT2a, 88% for pT2b, 77% for pT3a, and 44% for pT3b. Our data revealed overall 10-year PSA-recurrence-free survival of 65%, including 80% for pT2 and 51% for pT3–4 (Figure 100.11a). Compared to RRP [123–134], the oncologic outcome was similar (Table 100.9). Also in T3 stages oncologic outcome was favorable, although this was based on a multimodal approach [28, 29] as previously published for open surgery [134–138].

The multicenter study published by Vickers analyzed the learning curve of LRP based on PSA recurrence-free status [139]. In an earlier RRP study, it was identified that 250 cases needed to be performed by a surgeon to achieve a plateau. In the LRP series including more than 5000 patients, this plateau was reached after 750 patients. However, there was an ongoing improvement (Figure 100.12), indicating some advantages attributed to video-endoscopic surgery.

### Survival data

Clinical progression-free 10-year survival was 97% for pT2 and 81% for pT3 (Figure 100.11b). We observed a local recurrence in 3% of pT2 and 13% of pT3/4 cases managed mostly by early adjuvant irradiation. Overall, 10-year survival was 96.8% for pT2 and 92.2% for pT3 (Figure 100.11c) [28, 29].

## Functional results

Evaluation of functional results after radical prostatectomy is difficult, because only a few comparative studies have used validated questionnaires [3, 97].

### Continence

To determine early continence, we introduced the urine loss ratio (URL) based on a micturition protocol following

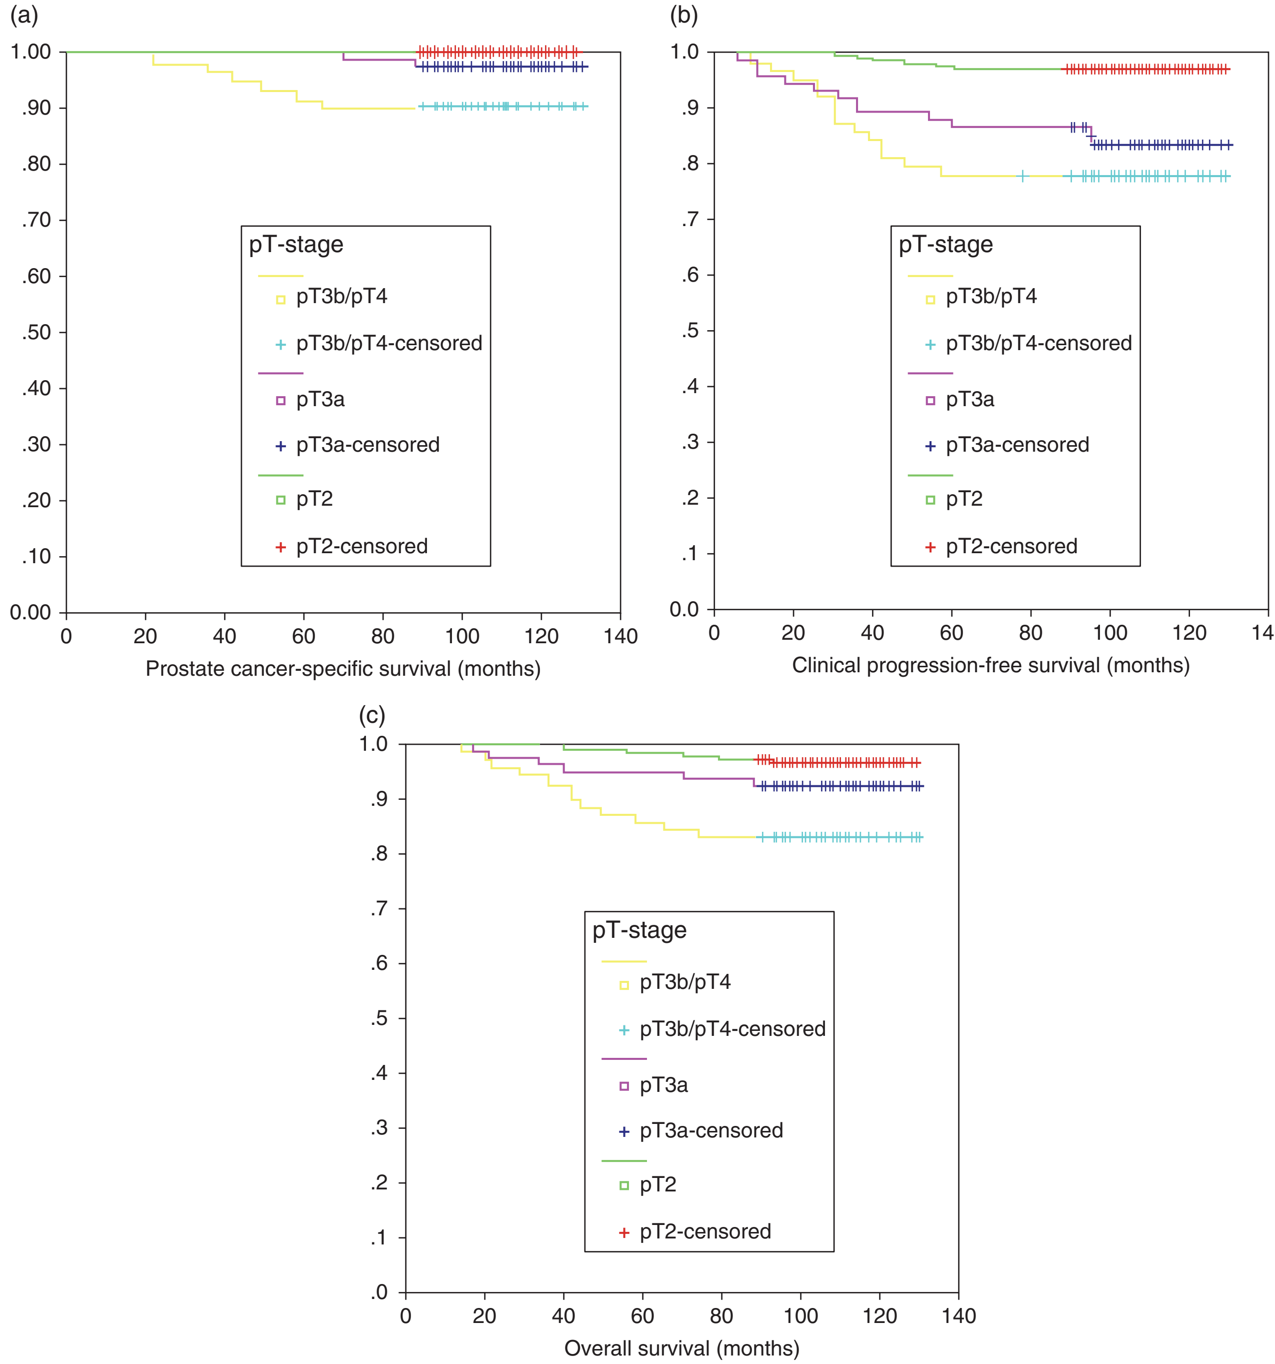

**Figure 100.11** Oncologic outcome of laparoscopic radical prostatectomy at 10 years follow-up (Heilbronn experience). (a) Prostate specific antigen (PSA) recurrence. (b) Clinical progression-free survival. (c) Overall survival.

catheter removal [140]. If URL is below 0.05, the probability that the patient will be continent after three weeks is 89%. Using URL, we compared our previous technique with and without posterior reconstruction and found no impact on URL (52% vs. 54%). When using the Heilbronn approach, the rate of minimal urine loss increased to 92% (Table 100.10).

One comparative study has shown higher long-term continence rates in RRP patients [89]. When evaluating the learning curve of LRP, continence recovery was better after RRP. Patients undergoing LRP had a twofold higher risk of being incontinent. In major series from referral centers, however, 12-month continence rates (66–95% vs. 60–93%) overlapped for RRP, LRP, and

RRP, retropubic radical prostatectomy; LRP, laparoscopic radical prostatectomy.

RALP (Table 100.11). Comparing our previous technique with the described technique of preservation of levator fascia and puboprostatic collar, we found a significant improvement with respect to early continence (Figure 100.13).

### Erectile function

Two studies have used validated questionnaires such as the International Index of Erectile Function (IIEF) [85, 141]. Three studies have compared RRP and LRP [85, 87, 89] and none showed any advantage favoring LRP. A single retrospective study comparing historical series after LRP and RALP demonstrated a statistically insignificant trend in favor of RALP [116]. No comparative study showed any significant advantage for LRP at 12 months (42–76% vs. 10–93%).

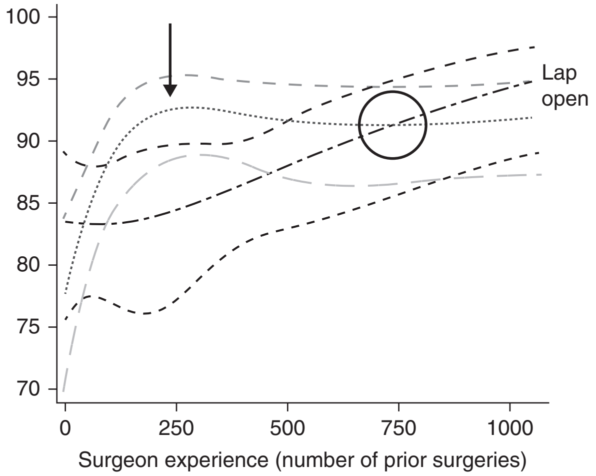

**Figure 100.12** Comparison of learning curves of laparascopic and retropubic radical prostatectomy [115]. Open surgeon reaches plateau of performance after 250 cases; laparoscopic surgeon requires 750 cases to reach similar level, but still improves beyond this level during the next 250 cases.

## Cost-effectiveness

Various cost calculations from the United States are available [142–146]. They suggested that LRP was more expensive than RRP (RRP US$5253–8596; LRP US$5058–10414). However, with the use of nondisposable instruments, completing LRPs in 3.4 hours, and discharging patients on postoperative day 2, cost equivalence between the two could be achieved [143]. Lotan et al. included RALP in their analysis and found a cost advantage of RRP of US$487 and US$1726 over LRP and RALP, respectively [144]. The shorter operative time (140 minutes vs. 160 minutes) and length of stay (1.2 days vs. 2.5 days) did not compensate for

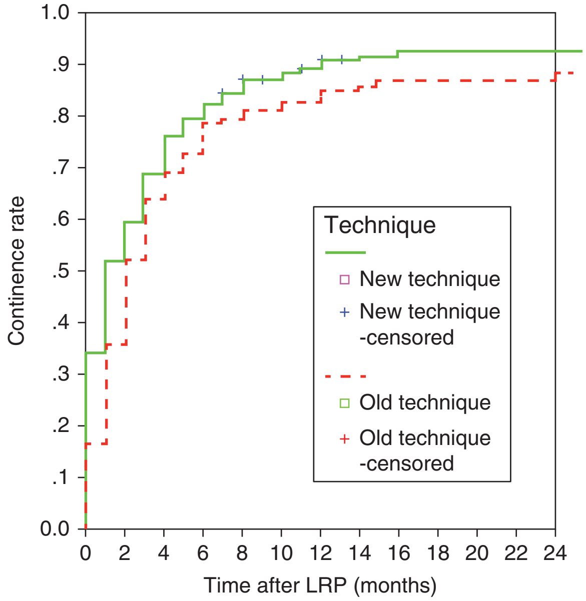

**Figure 100.13** Comparison of development of continence using the technique of preservation of puboprostatic collar (green) and levator fascia versus the standard technique (red). Kaplan–Meier curves demonstrate significantly higher rate of earlier continence. LRP, laparoscopic radical prostatectomy.

**Table 100.10** Impact of posterior reconstruction versus preservation of puboprostatic collar and levator ani fascia on early continence based on the urine loss ratio (ULR) following catheter removal (same surgeon, <70 years, pT2/3, bilateral nerve sparing).

| ULR[a] | No posterior reconstruction No preservation of puboprostatic collar | Posterior reconstruction No preservation of puboprostatic collar | Posterior reconstruction Preservation of puboprostatic collar |
|---|---|---|---|
| <0.02 | 55.2% | 52.3% | 92.3% |
| <0.05 | 22.7% | 18.2% | 7.7% |
| <0.11 | 9.4% | 18.2% | – |
| <0.16 | 6.4% | 9.1% | – |
| Total | 92.7% | 97.8% | 100% |

[a] Urine loss weight in pads/micturition volume (according to Ates et al. 2007 [140]).

the added expense of RALP. Moreover, in Germany the diagnosis-related group (DRG)-reimbursement system might be split into laparoscopic (pure or robot-assisted) and open prostatectomy. In such a scenario, LRP may become a very reasonable cost-effective alternative. This could be triggered by the end of the monopoly of Intuitive Surgical with introduction of other robotic systems [146].

## Perspectives on laparoscopic radical prostatectomy

### Ergonomic deficiencies

During LRP, surgeons suffer from high levels of mental and physical stress. After 4–5 hours, the fatigue syndrome sets in, characterized by mental exhaustion and reduced dexterity and capacity for good judgment [147, 148]. Back pain is common [148]. The force required to control the laparoscopic instruments can be six times greater compared to open surgery, and the problem is magnified further by the non-ergonomic design of the handles [149]. The assistant is also in a high-risk ergonomic position, created by the left leg bearing 70–80% of body weight over time [150]. Even if the da Vinci system has optimized the ergonomics of laparoscopic surgery, it still has limitations and is not cost-effective. Therefore, a significant effort needs to be invested to improve the ergonomics of laparoscopy.

### Technical advances

**Improvement in video-technology**

The introduction of HD video-technology to surgical theatre procedures at the beginning of this century

| 0.15–1 ($n = 287$) | 122 (42.5%) | 85 (29.6%) | 22 (7.7%) | 58 (20.2%) |

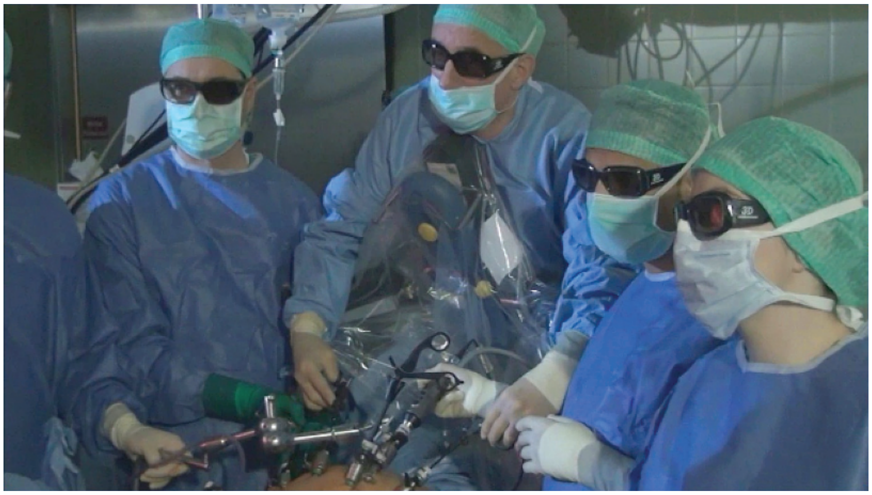

**Figure 100.14** ETHOS™ platform (ETHOS Surgical, Seattle, USA) to improve ergonomics during laparoscopic surgery. The surgeon sits over the patient's head during laparoscopic pelvic surgery. The armrest significantly improves ergonomics during suturing.

resulted in a considerable improvement in image quality (including resolution, brightness, depth, and magnification) compared with three-chip charge-coupled-device (CCD) technology or even one-chip technology, and enabled surgeons to safely perform complicated laparoscopic procedures, such as radical prostatectomy.

However, technology is under continuous development and 4K ultra-HD televisions are already being used in the consumer entertainment industry. In the last year first use of 4K in endoscopy and arthroscopy has been started (4K Arthrex, Munich, Germany; Olympus-Europe, Hamburg, Germany). These systems are a derivation of 4K digital-cinema standard, providing slightly lower resolution than a multiplex cinema at 3840 × 2160 pixels compared with 4096 × 2160 pixels, respectively. Consequently, 4K video-technology shows 8 million pixels compared with the 2 million pixels that full HD provides, enabling finer anatomical details and greater tissue texture than full HD, and a quasi-photographic emulsion of smoothness of the image [26].

Currently, 3D HD video-technology is available for 0° and 30° endoscopes, but polarized glasses, with a consequent reduction of brightness of the image, are still required. However, HD technology might partly compensate for this loss of brightness. The use of six degrees-of-freedom (6-DOF) instruments (i.e. Radius, Dexteritè) require 3D video-technology for optimal application, because the third dimension (i.e. using a 6-DOF needle driver) cannot be completely perceived by the operating surgeon [26, 151].

#### Ergonomic platform

In 1999, a special chair was proposed with pedal switches to improve the ergonomics [152]. Since 2005, we have used a surgical support during LRP to reduce the stress on the knee joints; however, during anastomosis the surgeon needs to stand up. Recently, a specially designed ergonomic body support consisting of a platform with foot pedal, a semi-standing support, a remote control, and a chest support was presented [153]. Electomyography results showed an average reduction of stress on the muscle of 44% for the erector spinae, 20% for the semitendinosus, and 74% for the gastrocnemious muscle when using the chest support. The average reduction of stress on the muscle using the semi-standing support was 5%, 12%, and 50%, respectively. In 2010, first experiences were published for the use of a platform (ETHOS™, ETHOS, Seattle, USA) that allows the surgeon to sit over the patient's head [154, 155]. This may overcome all physical stress problems concerning rotation, unstable standing, and weight balance (Figure 100.14). In a study published in 2015 comparing the ergonomics of standard laparoscopy with laparoscopy using the second-generation ETHOS chair or using the da Vinci system, the use of the ETHOS chair improved ergonomics significantly. Surgeon's muscle pain score (i.e. neck pain, shoulder pain, wrist pain, back pain) was 32 for standard laparoscopy versus 16 for the use of ETHOS versus 4 for the da Vinci system ($P < 0.05$) [155]. A further study confirmed these findings for retroperitoneal surgery as well [156].

#### Image-guided surgery

Surgical therapy for a clinically localized prostate cancer has undergone a significant transition in the past several decades. With wide application of minimally invasive radical prostatectomy, there has been a renewed interest in image-guided navigation techniques that could potentially be used to supplement the tumor resection and visualization/preservation of neurovascular bundles. Although this area of research is still in its infancy, these imaging techniques hold significant promise in achieving ultimate goals of radical prostatectomy [157–159].

Recently, an augmented reality (AR) navigation system that conveys virtual organ models generated from transrectal ultrasonography (TRUS) onto a real laparoscopic video during radical prostatectomy was described (Figure 100.15). This system uses custom-developed needles with colored pins inserted into the prostate as

**Figure 100.15** Marker-based navigation during laparoscopic radical prostatectomy. (a) Segmentation of intraoperative 3D-TRUS image identifying suspicious areas and position of inserted needle (navigation aids). (b) Calculation of endoscopic visualized markers and virtual markers as shown in the 3D-TRUS. (c) Real-time projection of virtual 3D image on HD image (right monitor). If the virtual markers and real markers are exactly overlaying, the virtual anatomy fits to the real endoscopic image. For performance of laparoscopic surgery a monitor without overlay is necessary.

(c)

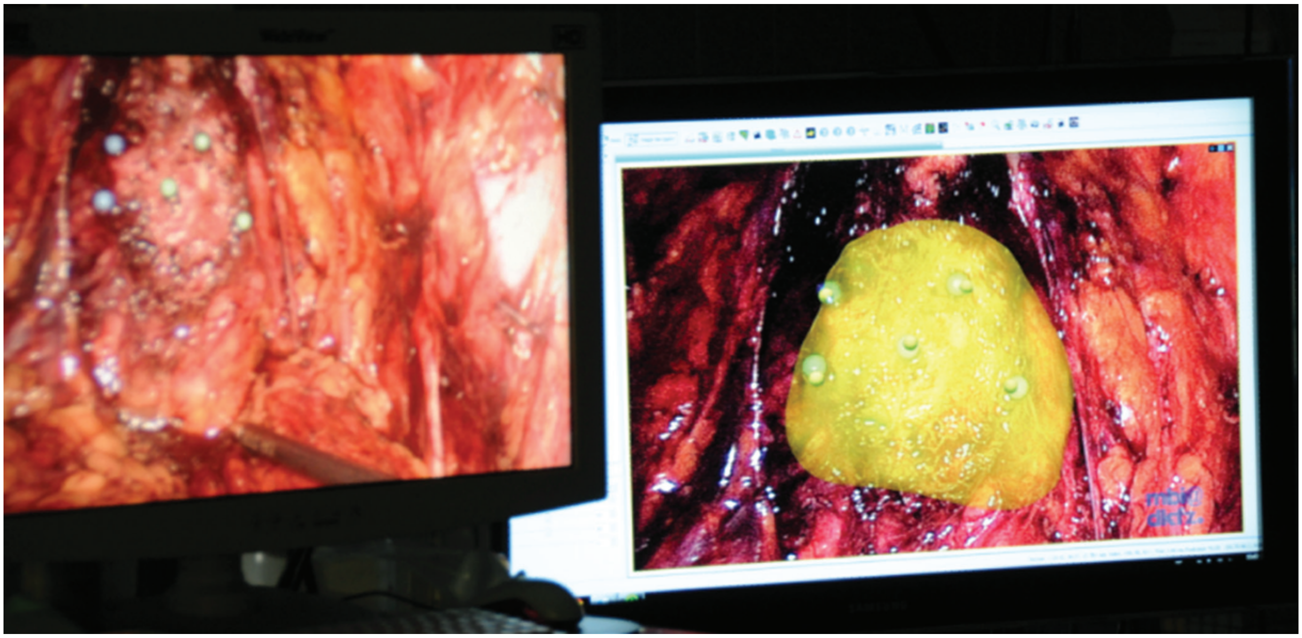

**Figure 100.15** (Continued)

soon as the organ surface is uncovered. By tracing the navigation aids in real-time, it allowed a registration between TRUS image and laparoscopic video based on the 2D–3D point correspondences. With this registration, the system correctly superimposed TRUS-based 3D information on an additional AR monitor placed next to the normal laparoscopic screen. First initial *in vivo* human application of the surgical navigation system in LRP was successful. No complications occurred, the prostate was removed together with the navigation aids, and the system supported the surgeons as intended with AR visualization in real-time [158, 159].

### Laparoendoscopic single-site surgery radical prostatectomy

Laparoendoscopic single-site (LESS) surgery has received significant attention in general surgery, where transvaginal cholecystectomy is increasingly performed. There are also reports of LESS radical prostatectomy using a periumbilical incision for port placement [160]. Interestingly, marketing also plays an important role in offering an "incision-less" removal of the gallbladder or prostate. The development of robotic systems for LESS surgery will significantly impact the ergonomics of this approach [161].

## Conclusions

There is no doubt that LRP has lost the race against RALP in the United States. Nevertheless, LRP has proven to be safe and provides at least similar functional and oncologic outcomes to RRP [162]. It will be interesting to see if future improvements, particularly concerning the ergonomics of the procedure, will impact on the role of LRP worldwide.

## Evolution of minimally invasive radical prostatectomy

Laparoscopic radical prostatectomy (LRP) was first described in 1997 by Schuessler et al. [1], 10 years after the arrival of laparoscopic surgery in 1987. Widespread adoption of LRP did not occur immediately, however, out of concern around the challenging vesicourethral anastomosis. Furthermore, there was no discernible advantage of LRP compared to open radical prostatectomy, suggesting that refinement of the technique was necessary. Additional development of the transperitoneal LRP approach was championed by Guillonneau and Vallancien in France in 2000, demonstrating a more reproducible and teachable technique, with operative times of a more acceptable 3 hours [2]. After concluding that LRP could be performed with comparable oncologic and functional outcomes, it started to be disseminated throughout Europe and select centers in the United States. The learning curve for LRP, however, remained high, primarily due to the technical challenge of the vesicourethral anastomosis. As a result, LRP was a daunting challenge for the novice laparoscopist and was performed only by skilled laparoscopic surgeons with sufficient experience to overcome the technical hurdles.

Soon after the advent of robotic surgery, the first robot-assisted laparoscopic radical prostatectomy (RALRP) was performed in 2000. This marked the beginning of a rapid shift in the surgical management of prostate cancer [3]. Use of the dominant robotic platform, the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA, USA), spread quickly throughout the field of urology, promising magnified 3D stereoscopic visualization, wristed instrumentation, and four robotic arms that proponents believed enhance the surgeons' ability to visualize the complex anatomy, retract, and suture. The seven degrees of freedom provided by the robotic arms simplified suturing of the complex vesicourethral anastomosis, in contrast to the technical challenge of pure laparoscopic suturing. Adoption of the da Vinci Surgical System was rapid and wide-ranging, including both large-volume tertiary care centers and smaller community hospitals. Without sufficient evidence to claim superiority of RALRP over LRP or open radical prostatectomy, the widespread use of the da Vinci system was driven by its popularity among surgeons and patients rather than proven benefit.

## Trends in practice patterns

Between 2003 and 2013 there was a 376% increase in the number of RALRPs performed, accounting for 22% of all radical prostatectomies in 2003 and 85% of all radical prostatectomies in 2013 [4, 5]. The dramatic shift also led to significant changes in practice patterns by urologists; LRP was largely replaced by RALRP and a growing number of urologists were no longer performing open radical prostatectomies. In 2013, 53.3% of urologist treating prostate cancer in the United States were exclusively performing RALRPs, a figure expected to rise [4], raising concerns about limited training opportunities for open radical prostatectomy. Furthermore, despite successful dissemination of robotic technology, practice patterns of urologists reflect a centralization of care for RALRP. Currently, the majority of open radical prostatectomies are performed by low-volume urologists, whereas RALRPs tend to be performed at high-volume tertiary care hospitals [6]. Despite the absence of randomized studies, current trends suggest that RALRP will continue to evolve into the predominant form of radical prostatectomy.

## Outcomes

Since the introduction of RALRP to the urologic community there has been considerable and continuous debate in the literature comparing open radical prostatectomy versus RALRP. In large part this controversy exists as a result of the absence of prospective randomized trials. As a result, reported outcomes typically arise from observational studies and single-center experiences with inadequate follow-up and poor methodologic quality [7]. Only recently have sufficient long-term oncologic and functional results been published, further validating the robotic approach to radical prostatectomy.

### Perioperative outcomes

Although long-term data are limited, perioperative trends for RALRP are well described. RALRP operative times are significantly greater than those for open radical prostatectomy and depend on surgeon experience [8]. Operative times during the early RALRP experience were in the 4–5 hour range [3], but as surgeon and operating room staff experience improved, operative times decreased significantly to 2–3 hours at centers of excellence [9, 10]. Nonetheless, some experienced robotic surgeons demonstrate operative times equivalent to those of open radical prostatectomy [9, 10].

RALRP also has significantly less blood loss than open radical prostatectomy, which results in a 4–7 times lower rate of perioperative blood transfusion [11–13]. As with LRP, pneumoperitoneum tamponades venous bleeding, which is the primary source of blood loss during radical prostatectomy. Other advantages to RALRP cited as factors optimizing hemostasis include improved visualization of bleeding, particularly at the prostatic apex and neurovascular bundles (NVBs), more precise ligation of the dorsal venous complex (DVC), and improved hemostatic energy sources [12, 14].

Postoperatively, there also appears to be a trend showing a reduced hospital length of stay, averaging 2–3 days for open radical prostatectomy and 1–2 days for RALRP in the United States [13]. Large series and meta-analysis have confirmed this trend of earlier discharge after RALRP in both the United States and Europe, but centers of excellence have actually demonstrated shorter lengths of stay with open radical prostatectomy [14–16]. Early experiences in the United States have also identified a significant reduction in postoperative pain for minimally invasive radical prostatectomy relative to open radical prostatectomy, reflected both as patient-reported pain score and narcotic requirement [17, 18]. When further examined with higher quality prospective data, the postoperative pain difference was of little clinical significance, signifying that both RALRP and open radical prostatectomy are well tolerated [18].

### Oncologic outcomes

Oncologic control remains the primary goal of any radical prostatectomy, which involves complete removal of the prostate and seminal vesicles with curative intent of clinically localized disease. To date, no randomized prospective study has been performed to compare oncologic outcomes of open radical prostatectomy and RALRP. However, since the introduction of the RALRP in 2001, a considerable amount of research points to RALRP, open radical prostatectomy, and LRP having equivalent long-term oncologic outcomes.

Surrogates of oncologic control of prostate cancer include positive surgical margin (PSM) status and biochemical recurrence rates. Early experience with RALRP was confounded by mixed results in the literature examining rates of PSMs. Many single-center experiences of RALRP identified worse PSMs compared to those from open radical prostatectomy [19], while other studies asserted that RALRP had superior rates of PSMs [20]. However, more comprehensive meta-analyses have favored RALRP as having lower PSM rates [11, 21], strengthened by lower rates of adjuvant radiation therapy and androgen deprivation therapy [21]. Tewari et al. and Novara et al., in large systematic reviews, reported mean PSM rates of 10.7% and 11% for pT2 disease, respectively [14, 15]. These studies were unable to detect a significant difference compared to open radical prostatectomy. Conversely, Pearce et al., in a matched comparison of 96 935 men who underwent RALRP and open radical prostatectomy from the National Cancer Data Base, identified RALRP as having a reduced risk of PSMs and use of adjuvant radiation [22], leading some to declare RALRP as having superior oncologic results [23]. Proponents cite improved visualization and dissection of the prostatic apex, where PSMs are more likely to occur [24]. In general, PSM rates are highly dependent on the experience of the surgeon [25] and patient characteristics. Known patient predictors of PSM for RALRP are identical to those seen in open radical prostatectomy: clinical stage, Gleason score, prostate volume, body mass index (BMI), and prostate specific antigen (PSA) [11, 15, 26, 27].

Biochemical recurrence and disease-specific survival, however, are more accurate assessments of oncologic outcomes. Overwhelmingly, RALRP has been shown to provide equivalent and durable oncologic outcomes relative to open radical prostatectomy at both intermediate [28, 29] and long-term [30, 31] follow-up. Novara et al., in a meta-analysis including five large series with 3–5 year follow-up, identified no difference in biochemical recurrence-free survival (BCRFS) rates when comparing open radical prostatectomy and RALRP [15]. Only recently has long-term oncologic data become available which has provided solace to skeptics of RALRP citing incomplete oncologic outcomes. In a series of 483 men, Diaz et al. demonstrated 10-year BCRFS rates of 85.7%, 62.4%, and 43.2% in low-, intermediate-, and high-risk patients, respectively, which is comparable to results from contemporary open radical prostatectomy cohorts [30, 32]. In a multi-institutional study of 1100 patients at 10-year follow-up, Abdullah published similar results [31].

### Functional outcomes

The primary functional endpoints of interest after radical prostatectomy, regardless of the approach, are rates of erectile dysfunction and urinary incontinence. These complications pose a significant impact on a patient's quality of life post prostatectomy and need for further intervention. Advocates of RALRP cite evidence of improved functional outcomes with RALRP, owing to enhanced visualization and dissection of relevant anatomy.

In the 3–6 months post prostatectomy, there is considerable improvement in urinary continence which appears to stabilize within 1 year. Significant evidence suggests that there is an earlier return to continence in men after RALRP compared to open radical prostatectomy, however no significant difference existed at 1 year [33–35]. In a large population-based study, O'Neil et al. revealed that men after RALRP experienced significantly improved urinary continence at six months compared to open radical prostatectomy [35]. No difference was found at 12 months. Findings of earlier return of urinary control in RALRP have been replicated in a number of other studies [11, 17].

As with other outcomes, many of the data examining potency for RALRP are highly influenced by the definition of potency, patient self-reporting, timing of evaluation, and use of erectile dysfunction medications. Despite these limitations, trends in the literature suggest RALRP confers superior preservation and earlier return of erectile function relative to open radical prostatectomy [17, 33] and LRP [36]. Ficarra et al., in a meta-analysis of studies reporting potency rates, revealed improved 12-month potency rates after RALRP compared to open radical prostatectomy (OR 2.84; 95% CI 1.46–5.43; $P = 0.002$) [37]. A combined cohort of 2438 men similarly identified significantly improved sexual function for RALRP at both 6 and 12 months. The RALRP cohort had lower rates of erections insufficient for intercourse, fewer poor quality erections, and less significant sexual bother compared to open radical prostatectomy [35].

## Complications

Compared to open radical prostatectomy and LRP, the types of complications for RALRP are similar; however, the complication rates may differ depending on the approach. A large meta-analysis of 15 studies published between 2008 and 2011 revealed an average overall complication rate of 9% for RALRP (ranging from 3% to 26%), 2% of which were complications grade 3 or greater [15]. Compared to open radical prostatectomy and LRP approaches, RALRP appears to demonstrate fewer overall complications [38, 39], although other studies have shown the opposite [40]. Not surprisingly, surgeon experience greatly influences the rates of complications, with a significant reduction seen after the learning curve [41]. Complications are also influenced by patient characteristics such as BMI [42], prostate volume [43], and tumor characteristics [15].

## Positioning and insufflation

Many of the early complications unique to RALRP were based on patient positioning; these are related to prolonged operative times, Trendelenburg and lithotomy positioning, and $CO_2$ insufflation. Lower extremity neuropathy (LEN), primarily from prolonged compression of the femoral and common peroneal nerves, has been reported at a rate of 1.3% [44].

Prolonged $CO_2$ insufflation and steep Trendelenburg have also been associated with complications such as increased intraocular pressure [45], increased intracranial pressures [46], and subcutaneous emphysema [47]. Hemodynamic and respiratory effects of $CO_2$ insufflation have been well described and include hypercarbic acidosis from $CO_2$ absorption and unintended consequences from increased intra-abdominal pressure, such as hypoxemia due to impaired mechanical ventilation, cardiovascular depression due to impaired venous return and vasodilation, and oliguria from decreased renal perfusion.

## Intraoperative complications

Intraoperatively, trocar placement and robotic instrument exchange have the potential for vascular and bowel injuries. Care must be taken to place and adjust robotic trocars and instruments under direct vision. Prompt recognition and repair of a bowel or vessel injury are vital to prevent serious bleeding and avoid more serious complications.

Rectal injuries, although rare, can occur at the apex during urethral transection and posterior dissection.

Two large meta-analyses of RALRP complications report rates of rectal injuries to be between 0.2% and 0.5% [14, 15, 39], however some early single-center series report rates as high as 1.5% [39]. Tewari et al. found significantly lower rates of rectal injuries during RALRP compared to LRP, but no difference existed relative to open radical prostatectomy [14]. Repair typically can be performed robotically and often involves a two-layer primary closure. However, more serious injuries may require open conversion or bowel diversion. If left unrecognized, rectal injuries can result in abscess formation and, more seriously, rectourethral fistula.

Ureteral injury, a rare complication occurring at a rate of 0.1–0.2% [14, 15], predominantly occurs during the dissection of the posterior vesicoprostatic junction and during approximation of the posterior wall of the vesicourethral anastomosis. Ureteral orifices must be identified, particularly in patients with a large median lobe, which often can be perilously close to the bladder neck and future anastomosis.

Open conversion has been reported at rates of 0.3–0.9% [14, 48] and is associated with significantly worse perioperative and functional outcomes. Patients who have had open conversion report greater rates of overall perioperative complications, prolonged hospital stay, and worse functional outcomes [49].

## Perioperative and delayed complications

In the immediate perioperative period, complications include anastomotic leak and thromboembolic events. Compared with open radical prostatectomy and LRP, RALRP provides improved dexterity and visualization of the anastomosis during suturing, which may explain why there tend to be fewer urine leaks and, later, fewer bladder neck contractures [14]. Proponents believe the reduction of anastomotic leak to be related to superior watertight approximation of bladder and urethra. Urine leaks and bladder neck contracture occurred on average in 1.8% and 1.4% of patients, respectively; this is significantly less than open radical prostatectomy [15, 50].

Because thromboembolic events are infrequent, the American Urological Association (AUA) continues to advise against routine use of perioperative prophylactic anticoagulation for radical prostatectomy [51]. Published series report deep vein thrombosis (DVT) occurring in 0–0.7% of patients [15]. In the setting of DVT, lymphocele which may be compressing the external iliac vein must also be ruled out with pelvic imaging. Treatment of DVT in the setting of lymphocele includes anticoagulation as well as drainage of the lymphocele, typically performed by interventional radiology. Asymptomatic and incidentally found lymphoceles do not require drainage.

## Perioperative care

### Patient selection

Indications for RALRP are the same as those for open radical prostatectomy and LRP, which is clinically localized prostate cancer. Few absolute contraindications exist; patients who are unable to tolerate pneumoperitoneum due to cardiopulmonary comorbidities and those unable to tolerate Trendelenburg positioning, including those with increased intracranial pressure, are contraindicated. Patients who pose a greater operative challenge include those with prior benign prostatic hyperplasia surgery, prior pelvic surgery or radiation therapy, prior inguinal hernia operations with or without mesh, and prior hormonal therapy. These patients often have significant adhesions and complex anatomy, requiring longer operations at a higher rate of both intraoperative and perioperative complications. Salvage RALRP is a particularly challenging procedure due to higher rates of tissue adhesions and dense fibrosis. Patients undergoing salvage RALRP should be counseled about higher rates of anastomotic leaks, challenging recovery of urinary continence and potency, and higher rates of rectal injury [52, 53].

### Bowel preparation

Prior to surgery, patients are typically managed with a form of mechanical bowel preparation, often based on institutional preference, to decompress the bowel and optimize visualization. Most commonly this is in the form of a fleet enema or oral laxative. Patients are often limited to a clear liquid diet 24 hours prior to surgery.

### Extraperitoneal versus intraperitoneal approach

Although there may be advantages and disadvantages to each approach, the decision to choose intraperitoneal versus extraperitoneal RALRP is heavily based on surgeon preference. Although early experiences with extraperitoneal RALRP suggested reduced operative time, shorter hospital stay, and improved functional outcomes, further evidence has shown no difference in outcomes compared to transperitoneal RALRP [54]. Overall, the transperitoneal approach is most commonly performed by robotic surgeons. Relative advantages of the transperitoneal approach include greater working space, less complex trocar placement, and less $CO_2$ absorption [55]. The major advantages to the extraperitoneal approach are related to being separated from significant adhesions from prior abdominal surgery and ease of simultaneous inguinal hernia repair with mesh [56]. Disadvantages include a smaller working space and challenging access in patients who have had prior extraperitoneal mesh during hernia repairs. Although there is a prevailing opinion that extraperitoneal pelvic lymph node dissection (PLND) is more difficult, lymph node yield has been shown to be equivalent for limited and standard PLND compared to the transperitoneal approach [57]. While an extended PLND has been described extraperitoneally, no study has compared the two approaches.

## Operative steps

### Patient positioning

Patients are positioned supine with arms tucked to the side on an operating table capable of steep Trendelenburg position. Eggcrate cushions are placed on either side of the arms to prevent compression injury to ulnar and median nerves. Use of shoulder rests should be avoided to avoid brachial plexus injury. The patient's legs are placed in low lithotomy in padded spreader bars with sequential compression devices to access the patient's perineum and provide space for robotic docking for the da Vinci S or Si models. For the da Vinci Xi model, the patient's legs are placed in a regular supine position. Tape or a securing strap should be placed across the patient's upper chest to keep him secured to the operating room table while in steep Trendelenburg position. Next, the patient is prepped and draped in the sterile fashion and a 16 Fr indwelling Foley catheter placed to drain the bladder.

### Pneumoperitoneum and trocar placement

#### Transperitoneal approach

The majority of urologic surgeons prefer the transperitoneal approach which affords greater working space relative to the extraperitoneal approach. Access into the peritoneum is obtained through a number of potential routes and is often dictated by surgeon preference. Veress needle placement, typically inserted at the level of the umbilicus, can be used to obtain pneumoperitoneum to a $CO_2$ insufflation pressure of 12–15 mmHg. Next, a skin incision is made for placement of the 12 mm trocar at the midline just above or below the umbilicus. For those with a high likelihood of abdominal adhesions, placement of the 12 mm trocar can be done under direct laparoscopic vision with a Visiport (Medtronic, Minneapolis, MN, USA) or with a dissecting trocar. Alternatively, open access and trocar placement via the Hassan technique is an effective and safe route to gain access under direct vision. The decision to place the trocar above or below the umbilicus is dependent on the length of the torso, with the optimal working distance 15 cm above the pubic symphysis.

The remaining ports should be placed under direct vision from the robotic laparoscope midline port. The Veress needle should be inspected to ensure no signs of bowel or vascular injury during initial placement and removed. Two 8 mm robotic ports are placed symmetrically two fingerbreadths below and 8–10 cm from the midline port. The minimum 8 cm distance between ports is required to prevent robotic arm clashing. With the da Vinci four-arm configuration, an additional 8 mm robotic port is placed on the left side 2–3 cm superior and medial to the anterior superior iliac spine (ASIS), approximately 8–10 cm from the left robotic trocar. Similarly, a 12 mm assistant port is placed on the right side, a similar 2–3 cm medial and superior to the ASIS and 8–10 cm from the right robotic trocar which is used for clip and suture access. On the right, a 5 mm assistant port for suction and irrigation is placed between the camera port and the right robotic trocar cranially. Either of the assistant ports can be used with the AirSeal (SurgiQuest, Milford, CT, USA) trocar for maintaining constant insufflation pressures. For obese patients, ports are placed more cephalad, paying special attention to the trajectory of the port during insertion into the abdomen to avoid skiving. Once the ports are in place, the lens can be switched to either a 0° or 30° down lens, depending on surgeon preference.

The robot is then docked to the patient, approaching the patient between the legs for S and Si models, or on the patient's side for Xi model. The ports are attached to each robotic arm, positioning the arms to avoid clashing outside of the patient. Robotic instruments are then advanced carefully under direct vision with monopolar cautery scissors in the right robotic arm, bipolar Maryland forceps in the left robotic arm, and ProGrasp forceps in the left lateral robotic arm. The bedside assistant is positioned on the patient's right, using the medial assistant 5 mm port for suction/irrigation and the lateral 12 mm assistant port for clip and suture access.

#### Extraperitoneal approach

Gaining access into the extraperitoneal space requires adequate understanding of the abdominal wall anatomy to avoid entering the peritoneum. A midline 1.5 cm infraumbilical incision is made followed by blunt dissection down to anterior rectus sheath with a mosquito or Kelly clamp. Using a Visport dissecting trocar under direct vision with a 0° laparoscope, sharp dissection is performed slightly left or right from midline until reaching the posterior rectus sheath. Next, the angle of the trocar is flattened and then advanced along and parallel to the posterior rectus sheath toward the pubis until entering the space of Retzius. Blunt dissection with the trocar is performed to each side. A balloon dilating trocar is advanced along the same tract and inflated under direct vision until the balloon edge reaches the lateral pelvic walls. Trocar placement is performed in a pattern similar to the transperitoneal approach, staying along a line drawn from the midline port to the ASIS on each side. For the extraperitoneal approach, however, there is only a single lateral 12 mm assistant port. Care must be taken to avoid entering the peritoneum during trocar placement to avoid insufflating the peritoneal space. Often, the lateral edges of the space of Retzius must be developed manually with a grasping instrument prior to docking of the robot. If the peritoneum is violated, a Veress needle or 5 mm port can be placed in the abdomen to vent the pneumoperitoneum.

## Posterior dissection

Access to the seminal vesicles (SVs) and vasa can be performed either anteriorly after transecting the bladder neck or posteriorly through a transperitoneal incision between the plane of the bladder and rectum into the pouch of Douglas. Using a 0° lens, the peritoneum is incised horizontally with the monopolar scissors in the midline. Blunt dissection is performed in the midline until the vasa and SVs become visible. The assistant or robotic fourth arm ProGrasp can aid in the retraction of the peritoneal fold and prostate with the suction device anteriorly. The vasa are divided and, slightly more laterally, the SVs can be freed out with electrocautery, Weck clips, and blunt dissection. It is important to stay medially during this dissection to avoid injuring the ureters inserting into the trigone laterally. The vessels at the tip of the SVs are divided with a clip. The ProGrasp can be used to expose the posterior plane of the prostate by retracting the SVs superiorly. Denonvilliers' fascia is entered just posterior to the SVs and the posterior plane is further developed between the prostate and Denonvilliers' fascia (anteriorly) and the perirectal fat (posteriorly) until the prostatic apex is reached. Alternatively, instead of a posterior approach, the SVs and vasa can be reached anteriorly after transection of the bladder neck. In the setting of a large median lobe, a posterior approach is preferred because the median lobe can obscure access to the SVs and vasa anteriorly.

## Bladder mobilization

After interfering abdominal adhesions are lysed, the space of Retzius is entered by cutting a U-shaped peritoneal incision that is extended laterally, transecting the medial umbilical ligaments until the vasa are encountered. The median umbilical ligament is also cauterized with the bipolar forceps and ligated. The peritoneal edge is retracted posteriorly and kept on tension while the extraperitoneal space is developed with monopolar electrocautery to drop the bladder and expose the anterior prostate. Blunt dissection of the extraperitoneal areolar tissue should be kept to a minimum to avoid venous bleeding into the operative field. When exposing the anterior prostate, the superficial dorsal vein is encountered and cauterized with bipolar electrocautery. The anterior periprostatic fat is removed to expose the anterior prostate and endopelvic fascia laterally to optimize visualization and is sent for pathologic evaluation.

On the lateral edge of the prostate, the endopelvic fascia is sharply incised from the prostatic base and extended toward the apex to the urethra. The Maryland forceps or ProGrasp can be used to retract the prostate cranially and medially to provide tension to the endopelvic fascia during dissection. As the fascia is cut, the muscle fibers of the levator ani should be preserved and brushed laterally. The use of electrocautery is minimized to reduce collateral injury to the nearby NVBs. Next, the puboprostatic ligament is incised, exposing the deep dorsal venous confluence. Care must be taken to avoid entering the DVC, which can result in bleeding that obscures the operative field.

## Dorsal vein stitch

Once the prostatic apex is exposed laterally, the dorsal vein can be ligated to minimize venous bleeding. After exchanging the left and right arms for needle drivers, a barbed deep dorsal stitch is advanced underneath the DVC and anterior to the urethra. The stitch should be placed as far distally from the prostatic apex to prevent violation of the prostate during apical dissection. The Foley catheter should be manipulated to ensure it is not incorporated in the suture. A second, more superficial bite across the DVC is made and the suture is tied to obtain hemostasis. Alternatively, the dorsal vein can be ligated with a laparoscopic stapling device in a similar fashion, but with a higher cost.

## Pelvic lymph node dissection

If a patient's preoperative risk of lymph node metastasis is sufficiently high, a bilateral PLND is performed at the surgeon's discretion. Typically, a PLND is unnecessary if the patient is low risk or if a preoperative nomogram predicts the risk of lymph node metastasis is less than 2%. The European Association of Urology (EAU) and National Comprehensive Cancer Network (NCCN) recommend an extended lymph node template, but the AUA lists this as an option. The dissection begins with the identification of the external iliac vein and, with gentle lateral traction of the vein, the lymph nodes are separated from the lateral pelvic sidewall as they course inferiorly to the vein. The obturator nerve is identified posteriorly as the lymph node packet is retracted medially. Dissection is carried out toward the obturator fossa caudally and the iliac bifurcation cranially. Hem-o-lok clips (Teleflex Medical, Research Triangle Park, NC, USA) are placed on the distal and proximal ends of the lymph node packet, paying particular attention to avoid entrapment or injury to the obturator nerve.

### Bladder neck transection

Identification of the bladder neck is performed primarily with repetitive retraction of the Foley catheter by the assistant at bedside and observing the border between the bladder and prostate. In addition, visual cues from palpating the Foley balloon with the robotic arms can further help locate the bladder neck. With monopolar electrocautery, a horizontal incision is made at the midline of the anterior bladder neck while maintaining traction on the bladder with the ProGrasp arm. The incision is continued until the Foley balloon is reached, staying medially to avoid bleeding from the lateral pedicles. The balloon is deflated and the tip is clutched by the ProGrasp forceps and retracted anteriorly toward the abdominal wall. The assistant provides countertraction on the Foley catheter to lift the prostate to expose the posterior bladder wall. The presence of a median lobe is identified at this time as well as the relative location of the ureteral orifices to avoid ureteral injury during both bladder neck transection and vesicourethral anastomosis creation. The posterior bladder neck is incised, navigating around any median lobe. Once through the posterior bladder wall, dissection of the posterior bladder neck off the prostate is performed by grasping the cut bladder edge with the Maryland forceps and developing a plane posteriorly at a downward 45° angle until reaching the SVs. Careful dissection is performed to avoid a positive margin on the prostate edge and to prevent buttonholing the bladder wall on the bladder edge. Sparing of the bladder neck should be attempted; however this may not be possible if a large median lobe or large-volume prostate is encountered.

If performing an early posterior approach, the SVs and vasa have already been freed and the ProGrasp arm can use the SVs as the new handle to retract the prostate anteriorly for managing the lateral pedicles. During an anterior approach, the vasa and SVs are encountered immediately after transection of the posterior bladder wall. While the assistant provides downward retraction of the bladder lip, the vasa are ligated and SVs are skeletonized. Care must be taken to reduce electrocautery use due to the close proximity of the NVBs laterally. The posterior dissection toward the apex is carried out in an identical fashion to the posterior approach.

### Lateral pedicles

Dissection and hemostatic control of the lateral pedicles is performed primarily in small tissue packets using Hem-o-lok clips. Electrocautery use should be minimized to prevent injury to the NVBs. Tension is maintained on the pedicle via lateral retraction of the bladder by the assistant to facilitate the separation of the lateral pedicle into packets with blunt dissection from either the scissor or closed Maryland grasper. Once the assistant places the clip in the defined packet, being careful to stay close to the prostate, the clip is released sharply with scissors. After the lateral pedicle is transected, attention is turned to preservation of the NVBs that course along the posterolateral aspect of the prostate as described by Walsh. The interfascial plane between the prostatic fascia and levator fascia is identified. With a combination of sharp cutting and blunt dissection, the NVBs are released along the fascial plane from the prostate toward the apex. Any significant arterial or venous bleeding can be controlled with careful placement of small Hem-o-lok clips, being careful to avoid entrapment of the NVB. Some authors, with hopes of preserving greater erectile function, have advocated a "high release" of the NVBs because of evidence suggesting that cavernosal nerves can course more anterior to the prostate than previously thought. In this situation, the lateral prostatic fascia is incised along the ventrolateral aspect of the prostate in a similar fashion with hopes of optimizing nerve preservation and revealing the so-called "veil of Aphrodite."

### Apical dissection

With the NVBs released, the DVC is incised with monopolar electrocautery scissors until the anterior urethra is reached, being careful to avoid capsular violation of the prostate. The Foley catheter is reinserted and the urethra is divided sharply a few millimeters distal to the prostate with hopes of preserving urethral length. Next, the posterior wall of the urethra is transected under direct vision, completely freeing the specimen. The specimen is inspected laparoscopically to ensure adequate margins.

### Vesicourethral anastomosis

Two barbed sutures are tied together at the tails and passed to the robotic arms, which have been exchanged for bilateral needle drivers. The anastomosis begins posteriorly with each suture coursing anteriorly on either side of the anastomosis, ensuring bladder and urethral mucosa are incorporated in each throw. The initial posterior throw of each needle is out-to-in on the bladder edge to keep the knot external to the anastomosis. During the posterior approximation of the anastomosis, the assistant can provide perineal pressure to facilitate placement of the urethral sutures. The running anastomosis is continued anteriorly, cinching the barbed suture after each throw by pulling the suture anteriorly to avoid tearing. The urethral catheter tip is passed into view by the assistant before each urethral throw to provide the best view of the urethral mucosal edge. Once the sutures meet anteriorly, they are tied together. Additional throws may be required to further approximate the bladder neck. The anastomosis is tested with the final 18 Fr catheter filled with sterile normal saline and the balloon is filled to 15 ml. Prostate and pelvic lymph node specimens are bagged with a specimen bag.

### Closure and postoperative management

After hemostasis is obtained, the robot is undocked and the ports are removed under direct vision to identify any bleeding from the trocar sites. The specimen bag is extracted through the midline port followed by fascia and skin closure. The 12 mm assistant port fascia can be closed with a Carter–Thomason suture. For the majority of cases, a pelvic drain is inserted through a 5 mm trocar site which is removed just before discharge if no urine or lymph leak is present. Narcotics are used only as needed and ketorolac is used frequently. Patients are typically discharged home within 1–2 days and catheter removal is planned within 10 days without a cystogram if an anastomotic leak is not present. On the night of surgery, patients are given a clear liquid diet followed by full liquid diet and regular fat-free diet for breakfast and lunch, respectively, on post-op day 1.

## Conclusion

Since the introduction of the RALRP, initial skepticism has been replaced with widespread adoption and belief that RALRP may soon become the new gold standard for radical prostatectomy. Supported by long-term functional and oncologic data, the RALRP provides equivalent outcomes. As future advances in robotic technology continue, minimally invasive radical prostatectomy will certainly continue to go through phases of transformation requiring additional studies to ensure patients are appropriately treated.

## Introduction

Optimization of the robot-assisted laparoscopic radical prostatectomy (RALP) principally focuses on three main outcomes: cancer control, continence, and erectile function. Innovations that address these areas have been applied preoperatively, intraoperatively, and postoperatively. Although the primary purpose of RALP is the safe removal of cancer, advances in our understanding of pelvic anatomy have allowed RALP to cause the least amount of collateral damage possible. Furthermore, the innovation of the robot-assisted technique allows for higher magnification and vision of tissues as well as increased range of motion with which to manipulate them. Consequently, the past two decades have seen several advances in radical prostatectomy technique, including in bladder neck dissection, prostatic nerve sparing, and urethral anastomosis.

## Preoperative optimizations

### Preoperative waiting period

A delay of six weeks following biopsy has traditionally been recommended to allow inflammation to subside. One single-surgeon retrospective study showed the surgeon was less able to perform bilateral nerve sparing when the procedure was performed within six weeks compared to waiting the six-week period, without seeing any differences in operative outcomes [1]. On the other hand, a large retrospective study showed no increase of adverse events or efficacy of surgery when performed prior to the conclusion of the six-week waiting period [2]. Further studies have shown that a six-week delay is unlikely to adversely affect patient outcomes. A large retrospective study found that adverse pathological outcomes did not develop by delaying prostatectomy until 150 days after biopsy for patients with Gleason <6 and prostate-specific antigen (PSA) 0–10, 60 days for patients with Gleason 7 and PSA >20, and 30 days for patients with Gleason 8–10 and PSA 11–20 [3]. Accordingly, given data showing no worse outcomes within six weeks of biopsy and the desire to avoid unnecessary stress and psychological harm to the patient, prostatectomy may be performed as soon as possible following biopsy.

### Preoperative magnetic resonance imaging

As advances in technology have rapidly progressed, utilization of pelvic magnetic resonance imaging (MRI) has taken on an important role in preoperative planning for patient counseling and surgical preparation. If undertaken post-biopsy, MRI is generally performed 6–8 weeks following biopsy to decrease artifact from hemorrhage [4]. Preoperative MRI, through the use of the Likert scale, can assess for the presence of clinically significant cancer, and can predict both biochemical recurrence and prostate cancer-specific mortality [5, 6]. Furthermore, information for the surgery itself can be gleaned from the MRI and utilized to predict surgical complexity [7]. The use of MRI preoperatively can also be used by the surgeon to assess the location and involvement of nerves and the likelihood of extracapsular spread and seminal vesicle invasion [4, 8]. This knowledge can then be used to direct intraoperative frozen-section analysis to reduce the rate of positive surgical margins (PSMs), though recent data suggests this advantage may only appear in cT1 tumors [9, 10]. Figure 102.1 shows a 3 tesla pelvic MRI with a right-sided lesion abutting the prostatic capsule, providing valuable clinical information about where

a wider dissection may be required. Despite the advantages of MRI, it does have certain limitations. The presence of post-biopsy inflammation can impair interpretation, and the sensitivity and specificity of the MRI is radiologist dependent [4]. The complexity of interpretation of the study strengthens the need for specifically trained radiologists interpreting the MRI. An additional limitation is the significant cost associated with the study, and availability and accessibility of high-quality MRI machines. Given its multitude of advantages, pelvic MRI has become an important tool for preoperative optimization.

## Weight loss counseling and preoperative activity level

Preoperative exercise and increased activity are recommended for several reasons. First, several studies have pointed to increased complications and surgical difficulty in patients with greater body mass index (BMI) [11, 12]. The second reason is the desire to limit venous thromboembolism (VTE) by increasing physical activity and avoiding stasis. Finally, patients with higher baseline activity levels preoperatively have comparatively improved quality of life following radical prostatectomy [13]. Increasing preoperative mobility may also help motivate the postoperative patient to resume normal activities more quickly.

## Smoking cessation

Smoking is a demonstrable risk factor for surgical site infections in addition to its other detrimental effects on the body [14, 15]. As a result, cessation counseling should always be provided prior to surgery. Even abstinence of smoking in a current smoker in the perioperative period can lead to decreased risk of infection [15]. There has also been some controversy as to whether smoking cessation has an impact on biochemical recurrence, though the most recent data demonstrate that smoking must be stopped at least 10 years prior to surgery to have an effect on disease recurrence [16].

## Erectile function evaluation

Preoperatively, it is also important to quantify baseline erectile function status for several reasons. First, quantification of baseline establishes realistic expectations for postoperative potency. A recent study demonstrated that even returning to baseline does not always lead to patient satisfaction, making preoperative counseling vital to postoperative satisfaction [17]. Furthermore, patients undergoing RALP have higher expectations with regards to recovery of erectile function than following an open procedure [18]. Preoperative erectile function can be evaluated at the time of biopsy to avoid the psychogenic influences of the immediate preoperative period [19, 20]. Potency and sexual function can be quantified using one of the many validated questionnaires of sexual health such as the International Index of Erectile Function (IIEF).

## Pelvic floor muscle exercises/training

Postoperative urinary incontinence is a potential outcome following RALP and should be approached proactively. A recent meta-analysis demonstrated that preoperative pelvic floor muscle exercises (PFME) might shorten time to recovery of continence. The meta-analysis demonstrated equivalent return to continence at one and six months, but a 36% reduced risk of incontinence at three months with usage of PFME at three months. Most suggested regimens involve physiotherapist guidance beginning 2–6 weeks preoperatively [21]. Yet, several of these studies suffer from biases including improper postoperative comparisons, limited postoperative PFME, or inconsistent continence criteria. Hoping to address this, a prospective randomized clinical trial found reduced risk of incontinence at both one and three months postoperatively for those undergoing 30 days of biweekly therapy [22]. However, in a 180-patient randomized clinical trial, conflicting results were found showing that three weeks of preoperative therapy had no improvement of continence following prostatectomy [23]. The discrepancy between the studies' findings may stem from the difference in definition of continence, with the first using patient's voiding diary and the second using a more stringent definition of 3 consecutive days of 0 g urine loss on a 24-hour pad. Although the data are not conclusive, many of the studies suggest a potential benefit of preoperative PFME without any significant clinical downside.

### Outpatient versus inpatient procedure

Though RALP has traditionally involved a mandatory inpatient admission, efforts have been made in recent years to test the feasibility of performing the RALP as an outpatient procedure. Two small studies conducted by experienced surgeons with carefully selected patients showed that >90% of the patients treated by these surgeons were able to undergo outpatient RALP without any observed detriment to surgical outcomes or patient satisfaction [24, 25].

### Choice of antibiotics

The American Urological Association (AUA) Best Practice guidelines recommend 24 hours of treatment with antibiotics to be started preoperatively for RALP. First-line therapy involves a first- or second-generation cephalosporin or an aminoglycoside or aztreonam with either metronidazole or clindamycin. Second-line antibiotics are ampicillin/sulbactam or a fluoroquinolone.

### Venous thromboembolism prophylaxis

A significant though rare source of morbidity and mortality following RALP stems from VTE, a term comprising both deep venous thromboembolism (DVT) and pulmonary embolism (PE). RALP patients are at risk for VTE due to the extended time spent in lithotomy position. Several studies have identified additional common risk factors for VTE including prior VTE diagnosis, smoking, obesity, and extended operating room time and requirement for lymph node dissection. Accordingly, in complex cases expert consultation is warranted. Studies examining the occurrence of VTE postoperatively found 17% prevalence of asymptomatic VTE and 0.5–2% symptomatic VTE. Critically, most symptomatic VTE events occurred following discharge, with peak occurrence occurring 2–4 weeks following surgery [26, 27]. Consequently, patients should be warned about the signs and symptoms of DVT and PE prior to discharge as well as their potentially catastrophic consequences. A 2009 AUA Best Practice Guideline suggests that all patients should have mechanical prophylaxis and patients with multiple risk factors should be treated with both mechanical and pharmacological prophylaxis. This includes both intermittent compression pneumatic boots as well as either low molecular weight heparin (enoxaparin 40 mg subcutaneous daily) or unfractionated heparin (5000 units every 8 hours subcutaneous starting during or after surgery) [28].

### Choice of equipment in the operating room and safety precautions

The choice of Foley catheter used in the RALP procedure has been shown to have significant postoperative effects. In particular Yee reported decreased stricture rate with the usage of 18 Fr compared to 22 Fr urinary catheters [29]. The extended time spent in Trendelenburg also poses an increased risk for facial edema and corneal abrasions, which can be prevented with the usage of patient safety goggles or other eye protection [30].

## Perioperative optimization

Although preoperative considerations are critical to optimize postoperative outcomes, careful and methodical technique within the operating room is also essential in providing patients with the best chance for a full recovery. All possible measures should be taken to maximize oncologic therapy as well as quality-of-life measures. As cancer control is the most critical component requiring successful treatment during RALP, it will be discussed throughout the following sections since its impact should be incorporated in all steps of surgery.

### Prostatic anatomy

At each step of RALP there is opportunity to optimize outcomes. This process begins with a thorough knowledge of all steps involved in RALP as well as the relevant pelvic anatomy. Although a detailed overview of surgical steps can be found in preceding chapters, the anatomy of the prostate and its nerve supply warrant additional discussion as their preservation is paramount in achieving rapid return to continence and erectile function.

The periprostatic nerve supply has been shown to form a hammock of neurovascular support extending around the base of the prostate and across its posterolateral aspect down to the apex. The hammock is comprised of the proximal neurovascular plate (PNP), predominant neurovascular bundle (PNB), and accessory distal neural pathways (ANP). All of these structures should be preserved to achieve ideal nerve sparing in any patient undergoing RALP, although oncological implications can sometimes make this impossible [31].

The PNP provides a source for integration of neurons surrounding the prostate. It courses lateral to the bladder neck and seminal vesicles before moving posteriorly along the base of the prostate to join the cavernous nerve. The PNB can be found in the lateral pelvic fascia (LPF) and is responsible for the nerve supply of the cavernosal tissue, urethral sphincter, and levator ani.

Since the LPF also contains the ANP lateral and posterior to the prostate, additional care should be taken with any manipulation of this region during dissection [31].

Care also needs to be taken during the apical and posterolateral dissection as this is the area most likely to have positive margins during RALP [32, 33]. A specific technique has been described for apical dissection whereby the conventional approach of ligating the dorsal venous complex (DVC) early is avoided as it can be detrimental to visualization. In one series, 209 patients were treated with a synchronous urethral transection through a retroapical approach and compared to 1665 that had previously undergone traditional anterior urethral transection after DVC ligation. The patients who underwent the novel technique had a lower apical PSM rate (1.4% vs. 4.4%; $P = 0.04$) despite those patient's having a higher incidence of >pT3a prostate cancer (16% vs. 10%; $P = 0.027$) [34].

## Bladder neck preservation

Bladder neck preservation through meticulous dissection of the muscle wall between the bladder and prostate has been shown to improve early return to continence in patients undergoing RALP. One retrospective analysis was completed with 599 patients who underwent RALP and had the level of bladder neck sparing graded from 1–4 with higher numbers denoting more aggressive bladder sparing. There were a higher proportion of patients in groups 3 and 4 compared to groups 1 and 2 who were continent at their three-month postoperative visit. However, by the 1-year mark there was no longer any statistically significant difference in continence [35]. A prospective study examined 1067 men who underwent RALP, 791 of whom had bladder-sparing surgery and 276 of whom did not. The group who underwent bladder neck sparing had less leakage ($P = 0.009$). Cancer control as defined by positive margins and biochemical recurrence was equivalent between both groups [36]. Nyarangi-Dix et al. completed a prospective, single-blinded randomized trial of 208 men who were assigned to either complete bladder neck sparing with urethra–urethral anastomosis or standard RALP. At 3, 6, and 12 months postoperatively patients who underwent bladder neck sparing were shown to have improved continence compared to controls (84.2% vs. 55.3%; 89.5% vs. 74.8%; 94.7% vs. 81.4%, respectively). The men who underwent bladder neck sparing also reported higher quality-of-life (QOL) scores at each visit. Furthermore, there was no significant difference between the two groups with positive margins (12.5% vs. 14.7%; $P = 0.65$) [37]. Bladder neck preservation is a safe technique with regards to oncological outcomes and can facilitate early return to continence.

## Preservation of puboprostatic ligaments

One area of debate during RALP is preservation of puboprostatic ligaments (PPL). Jarow described a reconstruction where the PPL are maintained in normal anatomic position to bolster support of the anterior urethra following radical retropubic prostatectomy (RRP) [38]. An additional study examined postoperative continence in 43 men following RRP where 25 had traditional apical dissection and the remaining 18 had preservation of the PPL. Postoperative questionnaires were completed showing a median time to continence of 6.5 weeks in the ligament-sparing group versus 12 weeks in the standard dissection group [39]. However, another study examined 149 men who underwent either PPL preservation alone, bladder neck preservation alone, or both and found that those who underwent either bladder neck preservation alone or in conjunction with PPL preservation had an earlier return to continence than those who had PPL suspension alone. This study also showed no significant difference in oncologic outcomes between the above techniques [40]. Figure 102.2 displays an intraoperative visualization of PPL sparing.

Another technique to preserve anterior attachments and space of Retzius includes a posterior approach to RALP. Galfano et al. completed 200 RALPs with avoidance of the Retzius structures in favor of dissection through the pouch of Douglas. Although this study was an internal comparison designed to assess the learning curve for this surgical approach, it achieved promising results with regard to continence and erectile dysfunction. Continence was achieved immediately in >90% of patients with 1-year continence rates of 96%. Erectile function had returned after one month in 40% of patients

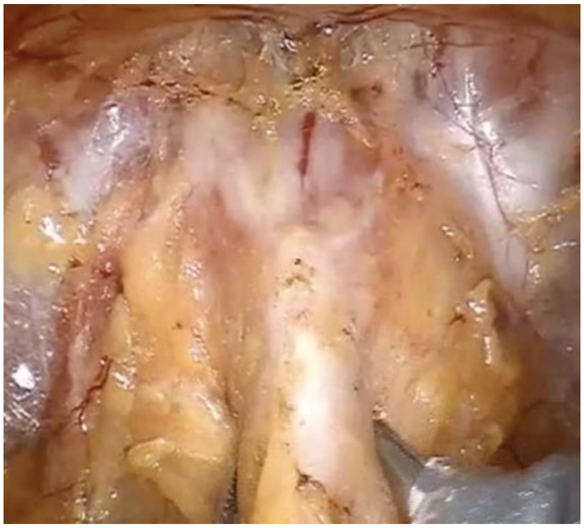

**Figure 102.2** Anterior view of bladder with sparing of puboprostatic ligaments prior to incision of bladder neck.

and by 1 year 70–80% of previously potent men had regained erectile function [41]. Further study into the posterior approach is certainly warranted and many robotic surgeons now champion this technique.

### Preservation of endopelvic fascia

Sparing of the endopelvic fascia (EPF) is another technique with promising results. Khoder et al. performed 231 RRPs for clinically localized prostate cancer without incision into the EPF and found earlier return to continence and potency with preservation [42]. Stolzenburg et al. performed 150 endoscopic, extraperitoneal radical prostectomies without incision into the EPF with 12-month continence rates of 94.3%. They describe a method by which the dissection plane is directly on the prostatic capsule, freeing the prostate laterally and preserving the EPF and PPF as well as the neurovascular bundles (NVBs) [43]. Preservation of the EPF should be attempted in patients where oncologic outcomes are not being sacrificed.

### Preservation of urethral length

Another operative technique to improve both time to and overall rate of continence is preservation of urethral and sphincter length (Figure 102.3). Multiple studies have examined the anatomic relationship between urethral length and continence. Paparel et al. examined 64 men who had undergone MRI before and after radical prostatectomy. Postoperative MRI was completed to assess for local recurrence. Increased mean urethral length was shown to have superior continence as graded on a 1–5 scale by patients. In addition, patients with more periurethral fibrosis were found to have worse continence rates [44]. Nguyen et al. described a new technique for anterior and total reconstruction of the urethra and bladder neck. He examined 274 men who had pre- and post-RALP MRI assessing urethral sphincter length found that in those with urethral sphincters >14 mm, 83% had return to continence (no pads or liner for security reasons) and 99% with the total reconstruction [45].

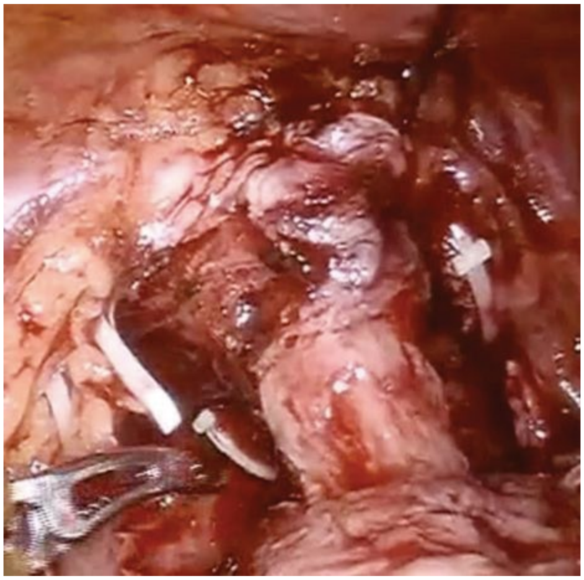

**Figure 102.3** Preservation of maximum urethral length in effort to promote postoperative continence.

### Neurovascular structure-adjacent frozen-section examination (NeuroSAFE)

Nerve sparing during RRP has long been an accepted principle for good functional outcomes after surgery. A relatively new technique, however, involves the utilization of frozen sections in the operating room to ensure that oncological outcomes are not compromised with nerve-sparing technique. The initial study by Schlomm et al. examined 11 069 patients who underwent RRP. During surgery, the entire lateral and rectal border of the prostate specimen was submitted for frozen-section analysis to determine surgical margin status. Of those patients who underwent NeuroSAFE, 1368 had positive margins, with subsequent negative margins being detected in 86% of those patients upon secondary resection. Overall rate of nerve sparing in these patients was significantly higher at all disease stages than without utilization of NeuroSAFE (97% vs. 81%; $P < 0.0001$). Furthermore, NeuroSAFE was found to have no increase in rates of biochemical recurrence [46]. Other studies have confirmed the ability of NeuroSAFE to detect positive margins and convert these patients to having negative margins with improved ability to complete appropriate nerve sparing [47]. Furthermore, the NeuroSAFE technique has also been found to be a feasible alternative specifically for RALP [48].

### Graded approach to nerve sparing

The oncological principles of NeuroSAFE can be augmented through combination with a graded approach to nerve sparing during RALP. A technique for standardized categorization of nerve sparing during RALP has been successfully utilized. Within this categorization, nerve sparing is graded 1–4, where grade 1 requires dissection immediately outside the prostatic capsule medial to the venous plane, grade 2 involves dissection outside the venous layer adjacent to the prostatic capsule (perivenous plane), grade 3 includes dissection through the lateral aspect of the LPF with some adipose tissue visualized on the prostate specimen, and grade 4 involves a wide dissection of the LPF and Denonvilliers' fascia (Figure 102.4). Grade 1 is reserved for patients with

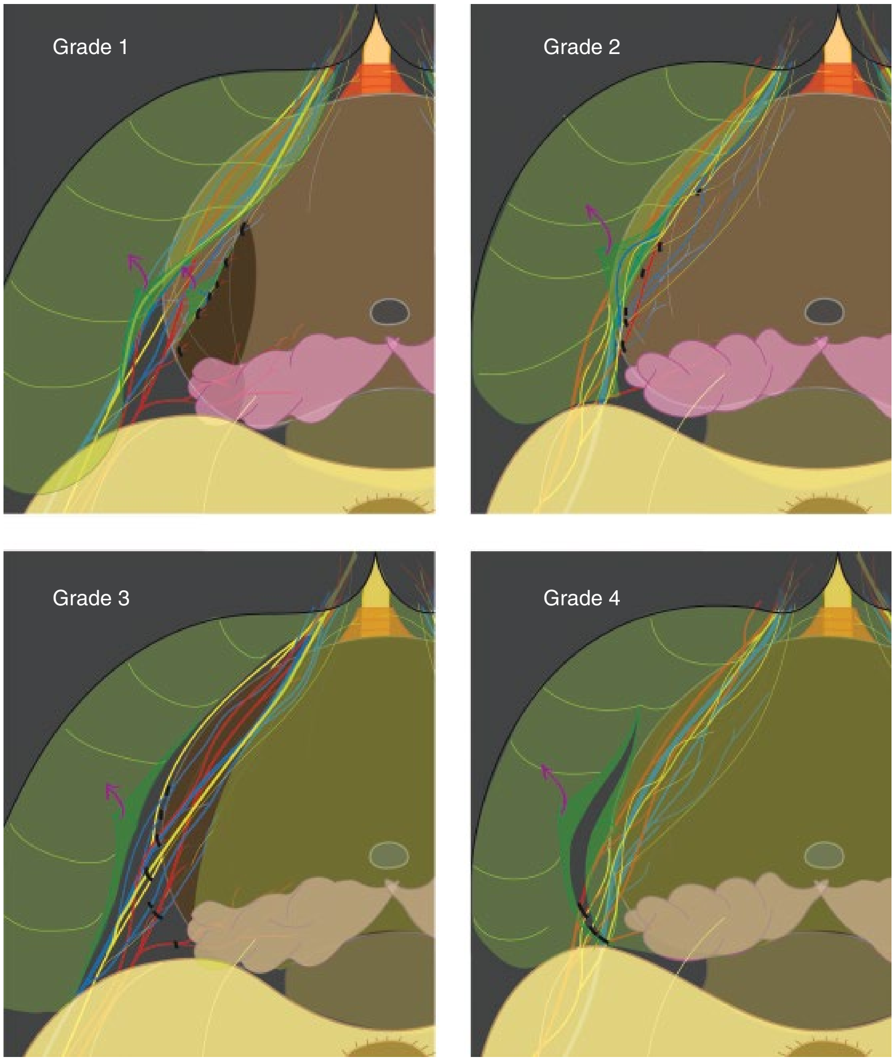

**Figure 102.4** Nerve-sparing grades. Grade 1: nerve sparing immediately lateral to prostatic capsule sparing all nerves. Grade 2: within the venous layer with sparing the majority of nerves. Grade 3: lateral to the venous layer with sacrifice of some nerve trunks. Grade 4: Non-nerve sparing. Key: Nerve fibers (yellow), venous plexus (blue), arterial plexus (red).

minimal risk of extraprostatic extension (EPE), grade 2 for patients with low risk of EPE, grade 3 in patients with moderate risk of EPE since some medial neural trunks are removed, and grade 4 for patients with known EPE. This grading system was retrospectively validated and, when utilized with NeuroSAFE, was able to establish better grades of nerve sparing without any compromise in cancer control [49]. Figure 102.5 shows an anatomic representation of the prostatic fossa following RALP with nerve sparing.

## Periurethral suspension and posterior musculofascial reconstruction

Another means by which some urologic surgeons feel they augment continence involves reconstruction of the bladder neck and urethra (Figure 102.6). In 1992, Klein examined 60 patients who had fascia posterior to the urethra incorporated into their vesicourethral anastomosis with complete continence (no need for pads) achieved in 83% of patients at three months and 88% at last follow-up [50]. Rocco et al. felt a combination of caudal retraction of the urethral sphincter and disruptions of the median posterior raphe were the main contributors to post-prostatectomy incontinence. In 2006 they reported a new technique to combat this problem where the posterior aspect of the sphincter was connected to residual Denonvilliers' fascia and tacked to the posterior bladder wall above the bladder neck. The "Rocco stitch" was examined in 161 patients who underwent RRP and compared to previous 50 patients in whom a traditional anastomosis was completed. The study showed a 90-day

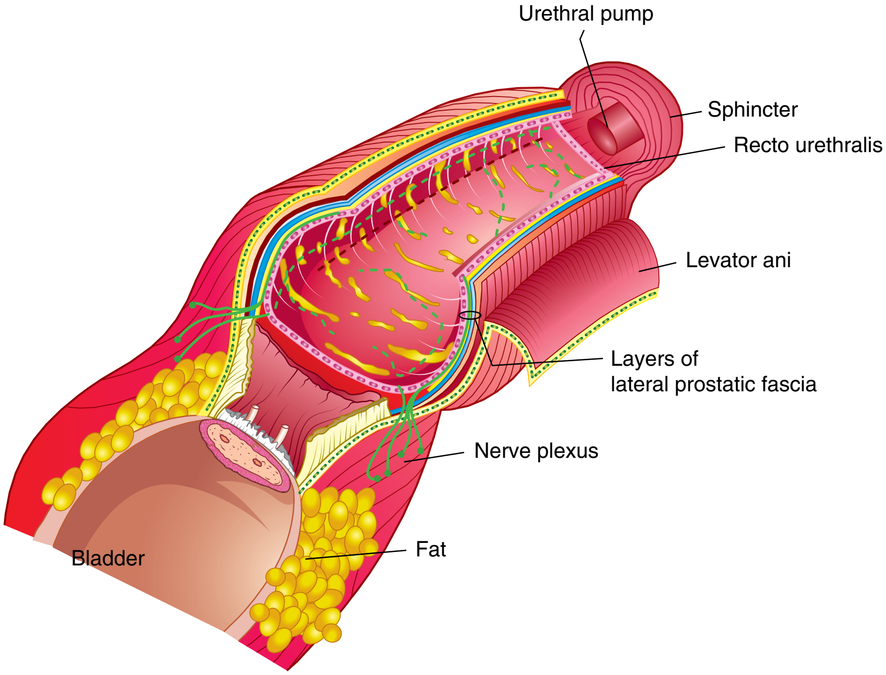

**Figure 102.5** Anatomic diagram of prostatic fossa after complete nerve sparing during robot-assisted laparoscopic radical prostatectomy.

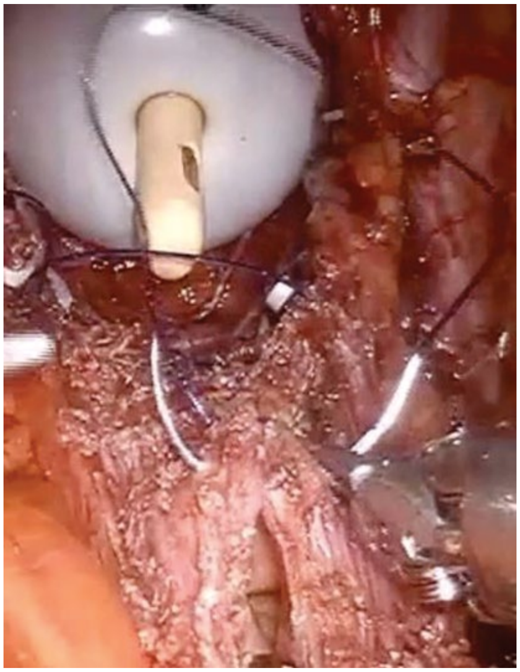

**Figure 102.6** Reconstruction of the bladder neck and posterior myofascial plane to promote postoperative continence.

continence rate of 86.3% in men who received the modified technique versus 46% in those who underwent standard reconstruction [51]. Nguyen et al. examined the effectiveness of posterior reconstruction of Denonvilliers' musculofascial plate and found a greater continence three days after catheter removal with the new technique, as well as an increase on average of 2 mm in postoperative urethral length [52].

At least four randomized trials have also been conducted studying the effect of modified reconstructive techniques on postoperative continence. A prospective, randomized trial of 60 men by Noguchi et al. examined a novel periurethral suspension technique and found the newer procedure had augmented continence at one (53% vs. 20%), three (73% vs. 40%), and six months (100% vs. 83%), respectively [53]. Menon et al. studied 116 men who were randomized to either a single-layer closure or double-layer urethrovesical reconstruction using the anterior and posterior rhabdosphincter for reconstruction. Continence was then examined at day 1, 2, 7, and 30 following catheter removal. The two-layer closure showed improved continence at every interval with the exception of the day 2 measurement. Despite impressive results with regard to continence in both groups, these results were not statistically significant [54]. Another prospective study examined 72 men who were randomized to either standard RALP or RALP with anterior suspension and posterior reconstruction. They found improved continence at one and three months in the modified reconstruction group (7.1% vs. 26.5%, $P = 0.047$; 15.4% vs. 45.2%, $P = 0.016$) with no significant difference in PSM or complications [55]. Finally, Sutherland et al. randomized 94 patients undergoing RALP to either standard running vesicourethral anastomosis or posterior rhabdosphincter reconstruction followed by standard anastomosis. There was no significant improvement in postoperative continence demonstrated with the modified reconstructive technique [56]. Although not all trials have demonstrated improvements in continence with posterior musculofascial reconstructive techniques, there is a potential benefit with early continence without evidence of increased complications. Similarly promising results with regard to periurethral suspension and reconstruction technique have been reported in other trials, further supporting the notion that implementing a similar strategy can optimize postoperative outcomes in patients undergoing RALP [57].

### Avoidance of traction and electrocautery

Throughout the dissection and reconstruction during RALP, great care should be taken to avoid excessive electrocautery. Multiple studies have shown histological and clinical damage is increased when a thermal technique is utilized. Ahlering et al. compared 125 men undergoing NVB preservation with and without the use of electrocautery and found that cases without electrocautery had a more rapid return to potency. Although patients who received electrocautery during dissection did regain potency two-thirds of the time, it generally took at least 12–18 months to recover function [58]. Mandhani et al. compared bipolar to monopolar electrocautery for RRP. They monitored temperature of the prostatic NVB during 25 cases of radical prostatectomy with a rise of 53.6 °C with monopolar and 60.9 °C with bipolar electrocautery, as well as an additional 3 seconds required to return to baseline temperature with bipolar electrocautery. Although the preceding difference was not statistically significant, it may give some credence to avoiding bipolar use during nerve-sparing components of RALP in favor of monopolar when electrocautery is required [59]. Despite other studies failing to show significant difference in return to potency with athermal technique, it is prudent to avoid extensive cautery during NVB dissection [60].

Avoidance of excessive traction is another critical component of RALP. Continuous pressure on the NVB can result in neuropraxia, axonotomesis, and even neurotmesis in severe instances. Wall et al. examined the effects of excessive stretch on tibial nerve fibers in a rabbit model and found that while 6% strain showed 70% return to normal function within 1 hour and complete regaining of function over longer time periods, 12% strain resulted in minimal return of nerve functioning after both 1 hour and the longer study periods [61]. One study examined the effects on 610 men undergoing RALP with and without assistant countertraction at the dissection of the NVB. The group who did not have assistant countertraction showed improved potency at five months (45% vs. 28%), although this difference disappeared by 12 months, suggesting that any nerve paralysis was temporary [62].

### Regional hypothermia

Hypothermia protocols have been used broadly in medicine to decrease inflammatory response and metabolic activity. Thorlacius et al. examined the effect of cooling on microvascular perfusion in hamsters and found that by reducing perfusion by decreasing temperature 8 °C, an inflammatory response in the tissue was avoided with a normal return to perfusion following a warming period [63]. Another study examined the effect of tissue cooling on microvascular response to tumor necrosis factor-alpha (TNF-α) and showed that decreasing tissue temperature by 10 °C for 60 minutes inhibited TNF-α-induced failure of capillary perfusion as well as leukocyte reaction to local injury [64].

Within the realm of prostate cancer specifically, several studies have examined the effect of local hypothermia on postoperative metrics. Finley et al. examined 47 patients undergoing RALP who received pelvic cooling with cold irrigation and endorectal cooling balloon. These patients underwent intraoperative temperature measurement and were compared to controls that underwent standard RALP without cooling. With a median temperature of 25.5 °C, the experimental group had a higher continence rate at three months (86.8% vs. 68.6%) and a faster median return to continence (39 days vs. 59 days) compared to the control group [65]. A follow-up study showed a 1-year pad-free continence rate of 96.3% compared to 86.6% in controls. In addition, there was a significant improvement in potency rates at the 15-month mark (83% vs. 66%; $P = 0.045$) in the hypothermic cooling group [66].

### Autologous nerve grafts and amniotic wraps

A more recent development in the effort to preserve erectile function and promote return to continence after RALP is the use of amniotic tissue around the NVB following dissection. Autologous nerve grafts using both the genitofemoral nerve and sural nerve have been attempted to restore cavernous nerve supply in radical prostatectomy patients without significant success [67, 68]. However, novel therapies with nerve wraps from amniotic tissue have demonstrated benefits with regard to preservation of continence and potency after prostate surgery. Patel examined the use of amniotic wrap around the neurovascular bundle during RALP to assess for possible acceleration of return to continence and potency in men with good preoperative measures in both categories. The study included 58 men who received dehydrated human amnion/chorion membrane (dHACM) wrap around the NVB who were then computer matched with 58 similar patients who did not receive treatment with dHACM wrap. The study showed improvements in time to continence (1.21 months vs. 1.83 months; $P = 0.033$) and potency (1.34 months vs. 3.39 months; $P = 0.007$). Although the dHACM group had higher continence and potency at the eight-week postoperative visit, those results were not statistically significant [69]. In the future, nerve grafts and wraps may provide a novel technique for further augmenting continence and potency following RALP.

## Postoperative optimization

Techniques to improve postoperative continence and potency do not end when the patient enters the recovery room. There are multiple methods by which patients can improve their outcomes after surgery through pharmacology, mechanical devices, and physical therapy.

### Pharmacologic therapy

The first study to examine the impact of medical pharmacology on post-RRP potency utilized intracavernosal injections (ICI) of alprostadil. In 1997, a prospective, randomized trial examined 30 potent men with clinically localized prostate cancer (Gleason 7 or greater) who underwent RRP with nerve sparing. Fifteen men were randomized to receive alprostadil injections three times per week for 12 weeks while the other group received no therapy. The group receiving alprostadil had a significant improvement in potency as defined by spontaneous erections satisfactory for intercourse at six months (67% vs. 20%; $P < 0.01$) [70].

Initial studies in animal populations have shown significant benefits in erectile function with phosphodiesterase 5 (PDE-5) inhibitors. Ferrini et al. examined fibrosis and loss of corporal smooth muscle in rats that underwent either sham operation, bilateral corporal nerve resection, or bilateral corporal nerve resection with postoperative vardenafil therapy and found corporal veno-occlusive dysfunction (CVOD) and decreases in inducible nitric oxide synthase (iNOS) in rats with corporal nerve resection. However, iNOS increased and CVOD improved in those rats treated with vardenafil compared to those who only received surgery [71]. These studies have been repeated with similar results in other animal studies utilizing sildenafil [72, 73].

Oral therapies have also been tested in the post-prostatectomy patient to determine their efficacy in improving potency after surgery. A randomized, double-blinded, placebo-controlled study examined the effect of nightly sildenafil treatment on patients who had undergone RRP with nerve sparing. Patients were given no therapy or one of two different dosages (50 mg or 100 mg) of sildenafil starting four weeks after surgery. Patients were then given 36 weeks of placebo or treatment and an eight-week treatment-free period. The treatment group showed 27% of patients who had experienced satisfactory sexual activity, while the placebo group showed only 4% of patients with that response. However, the extremely low rate of return to potency in untreated men compared to established levels in previously published literature caused a low overall response rate and early study closure [74]. Another randomized double-blinded study was completed in men who underwent bilateral nerve-sparing RRP and were treated with either placebo, nightly vardenafil, or on-demand vardenafil. The IIEF was used to assess patient's potency postoperatively and showed an improvement with on-demand vardenafil when compared to placebo [75].

Intraurethral suppositories have also been examined for potential efficacy with regards to treating erectile dysfunction after RRP. Raina et al. prospectively studied 91 males who underwent RRP with nerve sparing and were treated postoperatively with either Medicated Urethral System for Erection (MUSE) three times per week or on-demand PDE-5 inhibitors for desired sexual intercourse. Sexual Health Inventory for Men (SHIM) was used to assess potency and found that after six months, 74% of men who continued on MUSE had successful intercourse while only 37% of the on-demand group had achieved the successful intercourse. The study was flawed, however, with 32% of men in the MUSE group stopping therapy early secondary to penile aching or burning [76]. Another prospective, randomized trial compared men who underwent nerve-sparing RRP and were treated with either MUSE or sildenafil postoperatively. IIEF was completed in all patients at six months and 1 year, with a significant return to potency in the MUSE group at six months. By 1-year follow-up, however, there was no statistically significant difference between the two treatment modalities [77]. Although both MUSE and oral PDE-5 inhibitors appear beneficial in a return of erectile function following surgery, the discomfort associated with MUSE therapy in addition to its higher cost may make oral PDE-5 inhibitors a better option for patients who have undergone RALP.

PDE-5 inhibitors and local vasodilators are not the only medications with benefits in postoperative potency. Hong et al. prospectively analyzed 50 men without hypercholesterolemia who had prostate cancer and underwent RRP with nerve preservation. The patients were all given sildenafil postoperatively, with the second group also being prescribed atorvastatin 10 mg.

The experimental group exhibited higher sexual satisfaction as defined by IIEF scores ($P = 0.003$) at six-month follow-up [78]. There were minimal side-effects reported with the patients taking atorvastatin and this regimen should be considered in otherwise healthy men who undergo RALP for clinically localized prostate cancer.

Erythropoietin (EPO) injections are another pharmacologic intervention that has shown promising results with regard to erectile function in patients undergoing RALP. Initial animal studies have shown the expression of EPO receptors on neuronal and vascular tissue. They have also exhibited a more rapid recovery of erectile tissue function following cavernous nerve injury [79]. The presence of EPO receptors has been confirmed in human neurovascular prostate and penile tissue samples through immunohistochemical studies [80]. A retrospective analysis of 15 patients who received EPO prior to undergoing RRP with nerve preservation and were prescribed "on-demand" PDE-5 inhibitors showed higher IIEF-5 scores at 3-, 6-, and 12-month postoperative visits ($P = 0.05$) regardless of PDE-5 usage. The experimental group also exhibited a higher percentage of patients performing sexual activity, although those results were not statistically significant [81]. Other animal and retrospective analyses have shown benefits associated with angiotensin II receptor blockers (ARBs) in patients treated with these medications who underwent RRP with nerve sparing [82, 83]. Although these results appear promising, further examination with prospective, randomized trials is warranted to elucidate whether preoperative treatment with EPO and ARBs are warranted in all healthy, potent men undergoing RALP with nerve sparing.

## Mechanical therapy

Pharmacological therapy is not the only postsurgical treatment utilized to preserve potency. Vacuum erection devices (VED) have been employed with significant effect at promoting return of erectile function. One trial randomized 28 men who had good preoperative erectile function (IIEF >11) and underwent RALP with nerve sparing to either early VED use (one month) following surgery or late use (six months) after surgery for 10 minutes per day. The early-use group had higher IIEF scores at both three months (11.9 vs. 1.8; $P = 0.008$) and six months (12.4 vs. 3.0; $P = 0.012$) postoperatively. In addition, the patients who had early VED utilization showed a preservation in stretched penile length at six months while the late-use group showed a decrease in stretched length of approximately 2 cm ($P = 0.013$) during the same time period [84]. Other studies have also shown the preservation of penile length through early utilization of VED as well as potential increase in partner sexual satisfaction and return of potency [85, 86].

## Pelvic floor muscle training and electromyograph biofeedback

Many studies have examined the impact of postoperative physical rehabilitation on return to continence after radical prostatectomy. A Cochrane review was completed examining 50 distinct, randomized trials of patients who underwent radical prostatectomy, transurethral resection of prostate (TURP), or either RRP or TURP. These trials collectively included 4717 men, of whom 2736 had a conservative intervention. Although the authors concluded that there was not sufficient evidence to suggest that conservative interventions after RRP are effective at treating postoperative incontinence, most of their critiques were concerned with lack of standardization in outcome measures rather than the quality of individual studies. The main criticism revolved around the inability of most studies to blind participants and personnel [87]. Despite these deficits, many of the studies which specifically examined pelvic floor muscle training (PFMT) in post-RRP patients alone did show a benefit.

One study randomized 66 men (49 of whom completed the study) who underwent laparoscopic radical prostatectomy to either physical therapy with resistance, flexibility training, and Kegel exercises for 12 weeks to controls who did not complete these exercises. The experimental group reported an improvement in continence (73.1% vs. 43.5%; $P = 0.035$) at the study's conclusion [88]. A larger study randomized 300 consecutive patients who underwent RRP for clinically localized prostate cancer to a structured regimen of PFMT or a control group given no formal training in PFMT following catheter removal. After one and six months, the experimental group showed 19% and 94.6% continence, respectively, while the control group rates were significantly lower at 8% and 65% ($P < 0.001$). At the 12-month postoperative visit, however, there was no statistically significant difference in continence between the two groups [89]. Another randomized, controlled trial found significant benefit to preoperative training session in PFMT with close postoperative follow-up when compared to patients who only received a folder of written instructions on PFMT [90].

Goode et al. conducted a prospective, randomized controlled trial to examine post-RRP patients who were still experiencing incontinence 1 year after undergoing surgery. The trial included 208 men with persistent incontinence 1–17 years after RRP who were randomized to eight weeks of PFMT, PFMT with additional electromyograph (EMG) biofeedback and daily home pelvic floor electrical stimulation, or delayed treatment (control group). Bladder diaries completed by participants showed a 55% and 51% reduction in incontinence episodes in those patient's undergoing PFMT without and with EMG biofeedback/electrical stimulation, respectively, while the control group showed only a 24% reduction in incontinence episodes ($P = 0.001$). There was no significant difference between the two treatment groups [91].

EMG biofeedback has also been proven an effective treatment for post-RRP urinary incontinence. Yamanishi et al. completed a randomized, placebo-controlled trial where 56 men with severe incontinence were randomized to EMG biofeedback or a sham procedure. The active treatment group displayed a statistically significant improvement in continence compared to the group who underwent a sham procedure at one, three, and six months (36% vs. 4%; 63% vs. 16%, and 81% vs. 44%, respectively). Although continence rates were equivalent at 1 year, the results propose an additional method for prompting an earlier return to continence [92].

Electrical stimulation techniques have also demonstrated benefits in post-prostatectomy potency. A randomized, prospective trial of 68 men with prostate cancer who underwent nerve-sparing RRP included an experimental group who started stimulation of the frenulum with a penile vibratory device (PVD) for one week prior to surgery. IIEF-5 scores were higher in the experimental group 12 months after surgery (18 vs. 7.5; $P = 0.09$) [93].

## Conclusions

RALP is a dynamic operation which is continuously evolving. The process by which we optimize patients' postoperative status must incorporate a multifaceted approach to achieve both oncological cures as well as management of erectile dysfunction and urinary continence. Through preoperative planning, including smoking cessation and weight loss counseling, in addition to antibiotic and VTE prophylaxis we can build a solid foundation. With careful anatomic dissection, bladder neck, PPL, and EPF preservation we can further improve our patients' outcomes. Postoperatively, treatment with PDE-5 inhibitors, statins, and other medications in combination with VEDs, PMFT, and biofeedback can provide the best possible opportunity for our patients to maximize early return to full continence and potency. The above interventions, along with novel techniques such as hypothermia protocols and amniotic nerve wraps, make this an exciting time for urologists as well as an encouraging era for patients undergoing surgical treatment for prostate cancer.

## Introduction

Urological reconstructive surgery is performed for a variety of benign and malignant conditions, and has traditionally been performed using open surgical techniques. The transition toward minimally invasive surgery began when Schuessler et al. performed the first laparoscopic pyeloplasty in the 1990s [1]. The introduction of robot-assisted laparoscopic surgery has increased the use of minimally invasive technique for complex reconstructive urologic surgery [2]. The benefits imparted to the surgeon include enhanced 3D visualization, improved dexterity, greater precision, increased range of motion, and reproducibility.

Initial urologic experience with robotics was largely limited to prostatectomy, and by 2013 nearly 85% of prostatectomies in the United States were performed robotically [3]. As surgeon comfort and experience with robotic prostatectomy grew, robotic technology was adapted to reconstructive surgery, first with robot-assisted pyeloplasty and then by reports of robotic ureteroureterostomy, ureterolysis, ureteroneocystostomy, ureterocalicostomy, and others [4–9]. These procedures have maintained the benefits of minimally invasive surgery, including decreased postoperative pain, short length of hospitalization, and reduced postoperative recovery time, while demonstrating success rates comparable to those for the conventional open approach. Despite these successful series, minimally invasive, and specifically robot-assisted, reconstructive surgery can be technically challenging, which has limited its universal applicability [10–13].

Our institution has been performing robotic upper urinary tract surgery for over 10 years, and at the writing of this chapter we have completed over 300 reconstructive urologic cases [14]. Box 103.1 gives a summary of the common robotic instruments used in robotic reconstructive cases. The essential principles of robotic reconstructive surgery are surgical magnification, precise suturing techniques, well-vascularized tissue, watertight anastomosis, and judicious use of supportive tissues flaps. We continue to advance the field of reconstructive surgery utilizing new techniques such as buccal mucosa for ureteral reconstruction [15], the use of near-infrared fluorescence with indocyanine green (ICG) and dynamic ureteroscopy during robot-assisted ureteral reconstruction to help delineate the borders of ureteral pathology [16–18].

## Patient selection

Prior to bringing a patient to the operating room, the surgeon should determine if the obstructive ureteral pathology is extrinsic or intrinsic, document the length of the involved segment, and identify any surrounding pathology. Preoperative imaging is essential to illustrate the disease process, including length of the defect, and allow for accurate planning of the surgical approach. We advise the use of a three-phase computed tomography scan or magnetic resonance image of the abdomen and pelvis, with dedicated arterial and urographic phases to help identify if ureteric obstruction was from an intrinsic or extrinsic source.

The use of antegrade or retrograde studies help to provide dynamic imaging and aid in the evaluation. If the diseased ureter is severely stenotic and does not allow flow of contrast, simultaneous antegrade and retrograde radiography or ureteroscopy may be necessary to evaluate stricture length. If the patient presents with a ureteral

- Linear vascular stapling device (for omental wrap)
- Suction irrigator device
- Hem-o-lok® clip applier (Teleflex Medical, Research Triangle Park, NC, USA)
- Vessiloop (Getz Bros, Chicago, IL, USA)

stent in place, we prefer to remove it, and place a nephrostomy tube to allow for accurate evaluation of the affected ureter. We find that this practice decreases inflammation and allows easier identification of stricture and extent of disease.

Administration of a diuretic may be beneficial to obtain optimal ureteral imaging during the delayed urographic phase. Diuretic renal scans are useful to determine baseline function of the associated renal unit (in case nephrectomy is indicated) and to confirm obstruction in equivocal cases. Patients were considered obstructed if the $T_{1/2}$ was greater than 20 minutes after furosemide and/or if they had a delayed nephrogram on cross-sectional imaging with contrast. In some cases, patients presenting in acute renal failure or with intractable symptoms underwent a decompression procedure with a nephrostomy tube placement before a renal scan could be performed.

The indications for each procedure will be discussed in the individual procedural sections that follow.

## Preoperative preparation

Before undertaking reconstructive surgery, the urologist must be familiar with the use of numerous techniques to address any condition of the kidney or ureter that might surface at the time of surgery. The preoperative surgical plan may be modified intraoperatively when faced with unexpected findings.

Although preoperative imaging can help to guide the informed consent process, patients must be involved in an extensive discussion regarding all possible options for upper tract or lower tract reconstruction, which can include pyeloplasty, ureterocalicostomy, transureteroureterostomy, ureteroureterostomy, buccal mucosa ureteroplasty, ileal ureter, Boari flap, psoas hitch, ureteral reimplantation, autotransplant, and possibly nephrectomy. As a guide for ureteral reconstruction, defects of 2–3 cm may be managed with ureteroureterostomy, whereas defects 4–5 cm are better managed via ureteroneocystotomy; a psoas hitch works well for defects measuring 6–10 cm, a Boari flap can be used for longer defects measuring 12–15 cm in length. Buccal mucosa ureteroplasty can be placed throughout the mid and proximal ureter and lengths of up to 8 cm have been used. In addition, an ileal ureter can be used to replace any length of diseased ureter (Table 103.1).

All possible operative interventions, including open, endoscopic, laparoscopic, and robotic, are thoroughly discussed with the patient during the informed consent process. In addition to bleeding, transfusion, and infection, patients undergoing robotic ureteral reconstruction must be aware of the potential for conversion to open surgery. The possibility of recurrence of ureteral obstruction should also be discussed, in addition to the need for long-term follow-up and the possible need for reoperation. Urinalysis is performed before surgery and any urinary tract infection treated accordingly, and preoperative antibiotics are given prior to commencing the procedure.

**Table 103.1** Reconstructive techniques by location with adjunct procedure.

| Location of ureteral pathology | Surgical technique | Ureteral defect (cm) | Adjunct procedure |
|---|---|---|---|
| Proximal | Pyeloplasty | 2–3 | Downward nephropexy |
| | Ureteroureterostomy | 2–3 | Omental wrap |
| | Ureterocalcostomy | 2–3 | Autotransplant |
| | Buccal mucosa ureteroplasty | 2–6 | Bowel interposition |
| Mid | Ureteroureterostomy | 2–3 | Downward nephropexy |
| | Ureterolysis | Any length | Omental wrap |
| | Buccal mucosa ureteroplasty | 2–6 | Boari flap |
| | | | Bowel interposition |
| Distal | Ureteroneocystotomy (reimplant) | 2–3 | Omental wrap |
| | Ureteroureterostomy | 2–3 | Boari flap |
| | Ureterolysis | Any length | Psoas hitch |

In our practice, we do not routinely place ureteral stents preoperatively, to avoid ureteral edema and potential masking of an intraureteral stenosis. In addition, if a patient comes to consultation with a stent in place, we elect to remove it one week prior to surgery. We elect to place a nephrostomy tube if the patient has pain or fever.

## Selected case indications

### Upper tract reconstruction

**Pyeloplasty**

This is indicated in patients with a proximal ureteral stricture and symptoms or radiographic evidence of ureteropelvic junction obstruction.

**Ureterocalicostomy**

This is indicated in patients with a proximal ureteral stricture and a scarred renal pelvis who have failed prior antegrade or retrograde endoscopic management, or in patients with an inaccessible intrarenal pelvis.

**Ureteroureterostomy**

This is indicated in patients with proximal or mid-ureteral strictures that have been refractory to endoscopic treatments and in patients with ureteral obstruction secondary to a retrocaval ureter. The length of the stricture should be short enough, 2–3 cm, for a tension-free anastomosis.

### Pan-ureteral disease

**Ureterolysis**

Robotic ureterolysis with omental wrap can be performed in patients with ureteral obstruction secondary to retroperitoneal fibrosis. This procedure can be done unilaterally or bilaterally as dictated based on the patient's clinical scenario. It is important to rule out the presence of lymphoma or other retroperitoneal malignancy, a frozen section of the retroperitoneal tissue is sent prior to proceeding with any ureterolysis procedure.

### Lower tract reconstruction

**Ureteroneocystostomy (± Boari flap)**

This is indicated in benign or malignant pathology which entails the resection of distal ureter and the need to bridge a gap of 4–15 cm. We work in a stepwise approach; if the defect is 4–10 cm we perform a ureteroureterostomy with the addition of a psoas hitch sometimes combined with a ureteral reimplantation to ensure a tension-free anastomosis. For large ureteral defects measuring 10–15 cm, a Boari flap combined with psoas hitch may be used.

## Operative setup for robotic reconstructive surgery

Careful consideration must be given to operating room configuration due to the varied components of the procedure, including the robotic approach and the cystoscopic/ureteroscopic evaluation. Practical consideration must include positioning of the screens for the cystoscopic tower as well as the video tower for the robot.

## Patient positioning and preparation

The operating room setup depends on the location of the proposed reconstruction. For upper tract ureteral reconstructions we place the patient in a flank position similar to that used for a partial nephrectomy (Figure 103.1). This position is modified to ensure that the ipsilateral arm remains in an anatomic position. Two gel rolls are placed behind the patient, one at the upper back and the other at the lower back and buttocks, to help maintain a 45–60° angle. A bolster is placed under the patient's axilla to prevent brachial plexus injuries, and a rolled-up foam pad can be placed between the upper shoulder and neck for additional support. The patient's lower arm is placed on an arm board, and foam pads are stacked on top of it to create a place for the patient's upper arm to rest comfortably.

To improve access for the superior robotic trocar we place ipsilateral, upper arm, in a neutral position and a tape sling is placed under the elbow for support. The lower leg is flexed at the hip and knee while the upper leg is positioned straight; a pillow is placed in between the legs, and sequential compression boots are also employed for deep venous thrombosis prophylaxis. The patient is secured to the table with 3-inch silk or cloth tape. Attention is paid to ensure that all pressure points are padded. Once docked, the table is maximally rotated to allow gravitational mobilization of the bowel.

For mid-ureteral surgery a lateral to semilateral decubitus position or a lateral decubitus position with the patient in a modified low-lithotomy position is employed to provide access to the bladder for ureteroscopy or stent placement. Again we pad the patient with gel pads, axillary rolls, and do not bend the ipsilateral arm. These maneuvers protect against nerve injury while allowing for simultaneous cystoscopy and ureteroscopy. The robot is docked at a 90° angle to the operating table with the robot in line with the camera trocars.

For lower ureteral reconstructions, the patient is placed in a low-lithotomy position, with the robot docked between the patient's legs with steep Trendelenburg, similar to a robotic prostatectomy. For pan-ureteral reconstruction we usually place the patient in a lateral or semilateral decubitus position. The patient's anterior superior iliac spine is placed directly over the flexion pivot of the operating table to allow for maximal patient flexion when desired.

In all cases, the bedside assistant and scrub nurse stand contralateral to the affected ureter to facilitate the passing of instruments. The screen for the robot is placed cephalad to the robot and the cystoscope tower is placed caudad to the robot to allow both the bedside assistant and the surgeon performing ureteroscopy to see their respective screens.

It is important to note that the positioning of the table and robot can be changed intraoperatively to access other areas of pathology throughout the urinary tract. This may require placing an additional robotic trocar and changing the position of the robotic arms.

## Trocar configuration

### Upper tract port setup

Four or five trocars are used. A camera trocar is placed directly above the umbilicus and two robotic trocars are

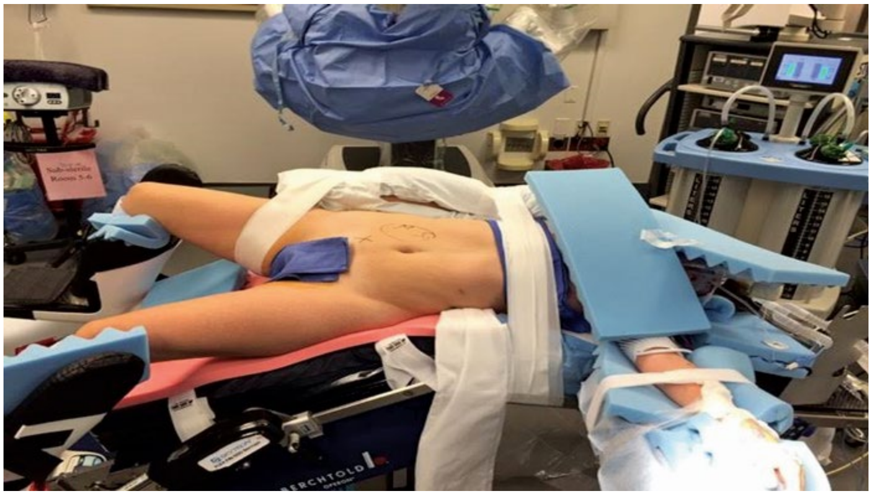

**Figure 103.1** Operating room positioning for reconstructive urology with ureteral access.

positioned 2–4 cm lateral and 8–10 cm away from the origin in either direction. These three trocars create a "V" shaped configuration. The fourth arm (optional) robotic trocar is placed in the lower quadrant 2 cm above the pubic bone in the midclavicular line, and the assistant trocar is just below the umbilicus (Figure 103.2a). For an obese patient this template is shifted laterally to ensure there is adequate access. Prior to docking, the table is maximally rotated to full flank to allow gravitational mobilization of the intestines. The robot is then brought in perpendicular to the operating table. The robot is docked at a 90° angle to the operating table with the robot in line with the camera trocars.

### Distal ureter port setup

Five trocars are used as follows. A camera trocar at the umbilicus, two robotic trocars to the left: one just lateral to the umbilicus in the midclavicular line and the other 2 cm superior to umbilicus in the anterior axillary line. We place a robotic trocar lateral and to the right of the umbilicus in midclavicular line and an assistant trocar above, between these two trocars (Figure 103.2b). The robot is then brought between the patient's legs.

Our institution uses AirSeal® (SurgiQuest, Milford, CT, USA) which provides stable pneumoperitoneum throughout the case through the assistant port. If AirSeal is not available, standard insufflation techniques may be used instead. In terms of access, we use the Hasson technique, and the Applied gel trocar (Applied Surgical, LLC, Birmingham, AL, USA).

## Specific techniques for reconstructive urology

### Cystoscopy and ureteral stent placement

If cystoscopy, with or without stent placement, or retrograde pyelography is needed we utilize the modified flank low-lithotomy position. Retrograde pyelography allows confirmation of the level and length of the compromised ureter. We also find that this helps reduce the number of inadvertent ureteral injuries during mobilization. In addition, the stent may be helpful in identifying the ureter with intraoperative ultrasonography in cases of severe fibrosis and inflammation.

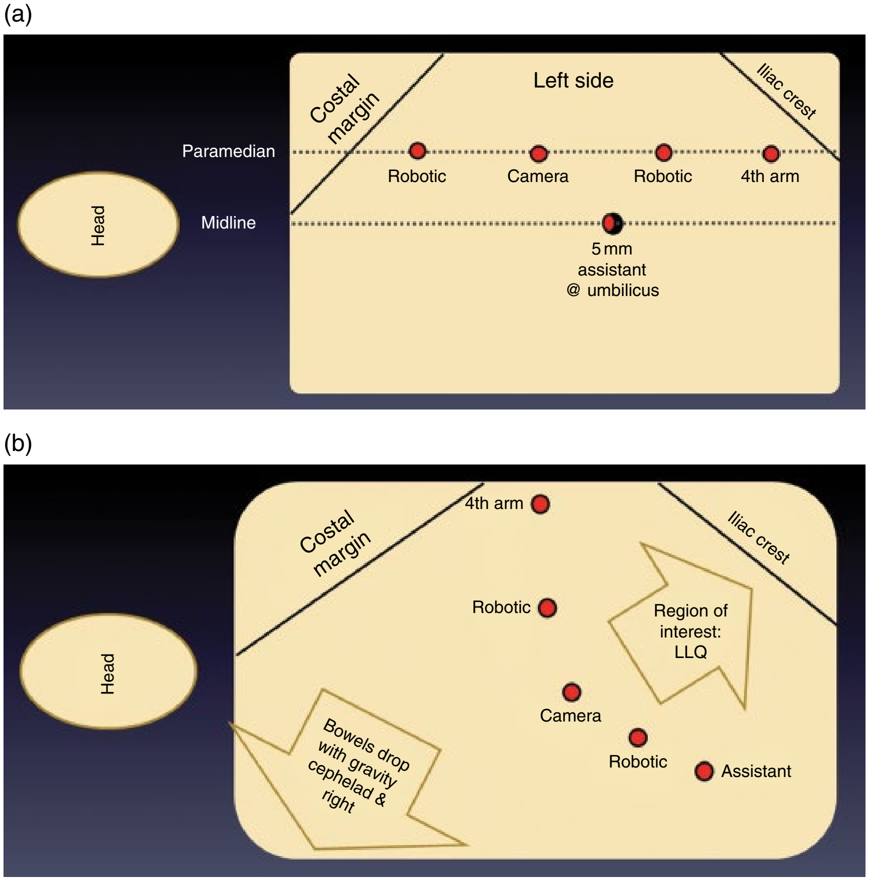

**Figure 103.2** Port placement for upper tract reconstructive urology. (a) Port placement for upper tract reconstructive urology: kidney, upper and mid ureter. (b) Port placement for bladder and distal ureter reconstructive urology.

## Surgical steps

### Exposure of ureter

Exposure of the entire ureter is of paramount importance; this is accomplished on the left by medializing the colon to the aorta from the spleen to the bladder, and on the right by medializing the colon and duodenum to the vena cava from the liver to the bladder. Having the table rotated so that the patient is in flank helps with this exposure. The console surgeon utilizes the bipolar graspers in the left hand and the curved robotic scissors in the right, while the bedside assistant uses a suction/irrigator. The amount of ureter that needs to be exposed is procedure and patient specific, but we find that this technique can easily allow exposure of the entire retroperitoneum, clearly demonstrating landmarks such as the gonadal vessels, iliac vessels, and lower pole of the kidney. We have also utilized intraoperative ultrasonography, intraureteral ICG and intraoperative ureteroscopy to identify the ureter [16–18].

### Exposure of kidney

We start by reflecting the colon medially along the white line of Toldt. The peritoneum overlying the inferior aspect of the kidney is then carefully dissected and mobilized off Gerota's fascia, which is then incised to locate the ureter which is carefully dissected free of the surrounding tissues. The ureter is traced cranially toward the renal pelvis, and meticulous efforts are made to avoid excessive handling/manipulation of the ureter and to leave tissue surrounding it to maintain perfusion. As dissection of the ureter approaches the renal pelvis, care should be taken to identify and preserve any crossing vessels.

### Exposure of the bladder

We start by dividing the urachus and developing the space of Retzius (between the medial umbilical ligaments) all the way down to the endopelvic fascia; this is very similar to a prostatectomy. Although rarely necessary, the contralateral superior bladder pedicle may be transected to increase bladder mobilization. Another technique to improve bladder mobilization is to incise the bladder horizontally and then stretch it vertically to the psoas muscle in a Heineke–Mikulicz technique. In all cases we perform a psoas hitch. We believe this minimizes tension at the anastomosis and keeps the path of the ureter lateral and away from bowel. We use 2-0 polyglactin or barbed suture on an SH needle to fix the posterior bladder wall to the psoas muscle tendon after identifying and avoiding the genitofemoral nerve. By performing a complete mobilization procedure we can insure a tension-free ureteral anastomosis.

When determining the site for ureteral reimplantation on the bladder, our goal is to always reimplant into the most posterior aspect of the bladder. We find that this prevents intermittent obstruction of the ureter during passive urine storage. To identify this we fill the bladder with 200–250 ml of saline and then split the overlying detrusor fibers to identify the mucosa. The mucosa is incised sharply and the neocystostomy is performed. In addition, a flexible cystoscopy can be used; simply dimming the light of the robotic camera and identifying the light from the cystoscope provides a clear location. Intraoperative cystoscopy is also very useful when additional bladder procedures are required, such as removal of a bladder diverticulum.

## Ureteral suturing

### Ureteral–ureteral

With the aid of da Vinci Potts scissors, we perform a spatulation of at least 10 mm. Once it is confirmed that a tension-free anastomosis can be performed, we use two 4-0 polyglactin sutures (a dyed and an undyed) on an RB-1 needle. We anchor the dyed suture laterally and the undyed suture medially. We place a double-J stent under direct visualization and the anterior anastomosis is then completed in a running fashion with the dyed suture, in a lateral to medial fashion.

### Ureteral–pelvic

Following removal of the diseased ureteropelvic junction and spatulation of the proximal ureter, we begin our anastomosis with a 4-0 polyglactin suture on an RB-1 needle placed through the apex of the spatulated ureter and at the most dependent portion of the renal pelvis. The posterior anastomosis is then performed in a running fashion. If redundant pelvis tissue has been excised, the remaining pyelotomy incision is closed using additional sutures.

### Ureteral–vesical

After the bladder mucosa has been entered we perform a running anastomosis using two 4-0 polyglactin sutures on an RB-1 needle, one for the lateral wall and one for the medial wall. This is followed with an intermittent 3-0 suture to reapproximate detrusor fibers over the neocystotomy and to obtain a watertight closure.

Following all ureteral reconstructive procedures, a closed suction drain is placed near the surgical field.

## Specific considerations

### Bilateral disease

In cases where bilateral ureteral surgery is needed (ureterolysis), we typically undock the robot, cover or close all trocar sites, move the robot to the contralateral side and reposition the patient with the contralateral side facing up. Our average repositioning time has been 20 minutes.

#### Tissue bolstering (omental wrapping or Gerota's fascia pedicle)

Bolstering the ureteral anastomosis with a well-vascularized tissue scaffold promotes healing for ureteral reconstruction. For mid or distal ureteral reconstruction we often use an omental wrap. The surgeon uses bipolar graspers in the left hand and ProGrasp™ forceps in the right, while the assistant uses atraumatic graspers to expose and isolate the omentum. Once the omentum is identified, the vessel sealer is used to harvest the omental pedicle. The most distal portion of the pedicle is brought underneath the ureter and tacked to the sidewall with a 3-0 polyglactin suture. Next, the lateral pedicle is tacked to the sidewall, allowing the entire omental flap to lay posterior to the ureter. The medial edge of the omentum, which is also medial to the ureter, is now wrapped anterior to the ureter and tacked to the sidewall. To prevent internal hernia, the window between the omentum and kidney should be closed.

We prefer to cover proximal ureter or ureterocalicostomy anastomosis with a vascularized pedicle of Gerota's fascia. We believe this improves healing, adds blood supply, and may protect from urine extravasation. As with all our ureteral reconstructions, a closed suction drain is placed near the reconstruction to detect urine leakage in the postoperative period.

#### Renal hilar control and use of intraoperative ultrasound for ureterocalicostomy

After the renal hilum is isolated, the psoas muscle is identified and the posterior surface of the kidney is dissected off the psoas. The kidney is then lifted anteriorly, placing the renal hilum on stretch. This retraction is supplied by the assistant or the fourth arm using a ProGrasp™ forceps, allowing the console surgeon to use two hands/instruments for the hilar dissection. A Doppler probe is used to identify the renal artery and vein, which is often encased in fibrotic tissue. The vessels are then dissected free from the surrounding tissue and isolated. A laparoscopic Doppler ultrasound probe is then introduced to identify the most dependent lower pole calyx. Gerota's fascia is cleared off this segment of kidney circumferentially. Prior to clamping the artery we ensure the patient is adequately volume resuscitated and administer 12.5 g of mannitol in an attempt to minimize ischemia–reperfusion injury.

#### Tension-free anastomosis

As in any reconstructive surgery, the main principles include the need to achieve tension-free, watertight anastomosis to allow for dependent drainage. If there is any concern that ureteral length is preventing a tension-free anastomosis, a downward nephropexy may be performed to allow the ureter to reach the calyx more easily and without tension. This is performed by mobilizing the kidney inferiorly and suturing it to the psoas muscle using a 2-0 barbed suture. If a tension-free anastomosis cannot be performed with this maneuver a renal autotransplant can be performed in an attempt to salvage the kidney. If kidney salvage is not possible, a simple nephrectomy should be performed. All surgical possibilities should be listed on the consent documentation, as part of the informed consent, prior to starting.

#### Exiting the abdomen

The operative site is examined for bleeding under low insufflation pressure, and hemostasis is achieved. The trocars are then removed under laparoscopic view. The robotic arm and assistant trocars generally do not require fascial closure but are simply closed subcutaneously.

## Postoperative management

Patients typically remain in the hospital for 1–2 days. On the first postoperative day, patients begin a clear diet, aggressive ambulation, and oral pain medication. The urethral catheter is removed on postoperative day 1 or 2 for a trial of void, and 8 hours later the output of the Jackson–Pratt (JP) drain is sent for creatinine analysis to rule out a urine leak. If the JP fluid analysis is consistent with serum and not urine, the drain is removed. Diet is advanced, and the patient is discharged. The stent is removed with an office cystoscopy in 4–6 weeks, and appropriate imaging studies are obtained thereafter.

## Tips and tricks

### Atraumatic ureteral traction

A Vessiloop® (Getz Bros, Chicago, IL, USA) can be placed around the ureter to aid the bedside surgeon in applying atraumatic traction on the ureter during dissection. Careful dissection is continued to free the ureter up to the area of stricture, at which point any of the above described maneuvers can be used to confirm the distal end of the stricture.

### Retrograde stent placement during ureterocalicostomy

Prior to completion of the anastomosis a wire is advanced through the open-ended stent into the pelvis. The double-J stent is placed in a retrograde fashion, under direct vision. Care must be taken if antegrade stent placement is elected, as this maneuver can creates significant tension on the anastomosis during the passage of the wire and stent.

### Obstructed kidney with concurrent stones

If stones are present, a flexible cystoscope or ureteroscope is introduced by the assistant through one of the trocars and then passed through the open lower pole calyx to examine the internal collecting system of the kidney. Any encountered stones are retrieved with a 1.9 Fr tipless nitinol basket (Boston Scientific, Natick, MA, USA).

### Use of indocyanine green during robot-assisted ureteral reconstruction

In select cases where preoperative imaging or intraoperative studies cannot fully visualize the ureteral stricture, secondary to periureteral inflammation which often coexists with the underlying pathology, the use of ICG may help to document the full extent of the ureteral disease. ICG aids in the identification of the proximal and distal ends of healthy ureteral tissue to help define the boundaries of the ureteral pathology. Specifically, this technique identifies poorly perfused ureteral tissue as dark green, and well-perfused tissue as bright green. This technique has since been used by other groups to minimize complications related to poor blood supply. [16, 17]. While ICG is used as an intravenous injection during partial nephrectomy, we use an intraureteral instillation of 5 ml for ureteral reconstruction. It must be noted that intraureteral ICG is an off-label use. ICG can be instilled either via a preexisting percutaneous nephrostomy tube or via a ureteral catheter, placed intraoperatively. We suggest that the surgeon waits 5–6 minutes after the ICG is instilled before activating the Firefly™ camera.

### Use of dynamic intraoperative ureteroscopy

Because ICG can be lost after ureteral transection, we have developed a technique which allows for dynamic ureteroscopy and concomitant fluorescent visualization, without the need for ureteral instillation. The light source filter of the ureteroscope can be changed to near-infrared setting and the Firefly camera will identify the ureteroscope's light as green, similar to the color of ICG (Figure 103.3a–d) [18]. We find this especially useful in complex cases which require significant reconstruction. Fluorescence imaging allows for confident and improved ureterolysis in the setting of significant scarring and fibrosis. This technique can be used for ureteral or renal pelvis reconstruction and we have successfully performed ureterolysis, pyeloplasty, and other robotic reconstructive cases with dynamic intraoperative ureteroscopy [19].

## Steps to avoid complications

Wide exposure is essential to identify the transition from healthy to diseased ureter as adjacent structures may be involved in the disease process. An athermal technique favoring sharp dissection is essential to avoid potential compromise of the blood supply to the already diseased ureter, which can develop into ischemia and urine leakage. The use of omentum provides vascularized tissue which promotes healing. A surgical drain helps to identify diagnosis and quantify postoperative urine leaks, which may delay urethral catheter and stent removal.

## Assessing treatment success

We use radiological imaging, renal scans, to determine postoperative success. If the postoperative renal scan identifies a $T_{1/2}$ of <20 minutes, there is no obstruction and the surgery was successful. For patients with ipsilateral preoperative renal function ≤25% that persists after surgery and a postoperative $T_{1/2} > 20$ minutes we rely on radiographic endpoints. We define radiographic success as an improvement in the drainage curve and/or improved hydronephrosis. This exception was made secondary to the fact that poor renal function can affect calculations by nuclear medicine scan. Other patients undergoing reconstructive procedures are assessed for resolution of obstruction with retrograde pyelogram and resolution of hydronephrosis with ultrasonography. Lastly, symptomatic improvement is assessed by history on follow-up visits.

## Identifying complications of robotic reconstructive surgery

### Intraoperative complications

General principles of perioperative care apply to patients having urologic reconstruction and include the use of bilateral sequential compression boots, prophylactic antibiotics, and generous padding to all pressure points. We must preface that there are limited data, from small case series, on robotic reconstructive procedures. However, overall, the intraoperative complication rate is low and there was no significant morbidity noted in published series of robotic reconstructive cases [5–9, 12, 13].

**Ureteral reimplantation**
One specific study compared open laparoscopic and robotic ureteral reimplantation in 130 patients. While there was a 5% rate of intraoperative complications in the laparoscopic group, most commonly inadvertent ureterotomies which

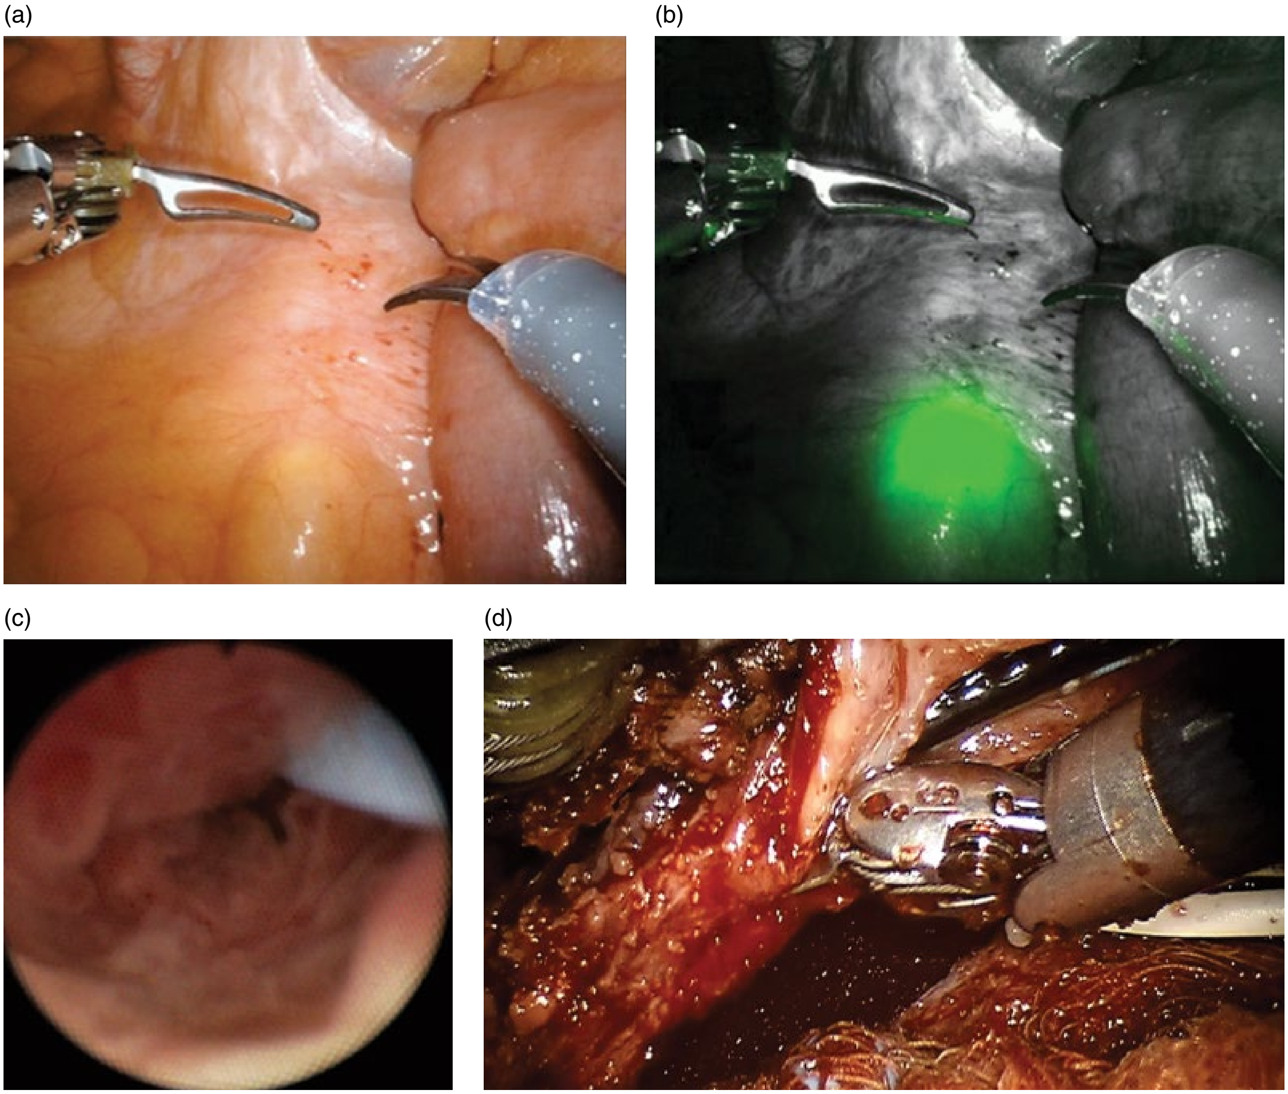

**Figure 103.3** The ureter in (a) white light and (b) fluorescence mode. The light of the ureteroscope within the ureter can easily be seen in fluorescence mode. (c) Ureteroscopic view of the strictured segment. (d) Ureteroscope seen after incision into the ureter, additionally the ureteroscope can be left in the ureter during anastomosis to prevent the misplacement of the suture into the back wall of the ureter.

were repaired intraoperatively and an enterotomy which required small bowel resection, there were no complications or conversations in the robotic cohort [12]. The authors noted the robotic approach provided superior visualization which made suturing easier and resulted in increased hemostasis and fewer complications. In addition, two studies with a total of 35 robotic procedures found significantly shorter hospital stay and reduced blood loss compared to the open surgical approach [9, 13].

**Ureterolysis**

Ureteral injury is the most common complication of ureterolysis [20]. These injuries should be repaired primarily, if possible, based on the extent and location of injury. An omental wrap or intraperitonealization should be performed to protect the ureteral anastomosis [21]. Robotic ureterolysis has been performed without morbidity and continues to be a safe technique. The magnification may facilitate identification of the ureter, and the use of limited tissue handling and the precision of robotic Pott scissors can help with dissection and prevent the risk of injury to the ureter [22].

## Postoperative complications

A review of the literature has identified that the majority of complications of robotic reconstructive surgery are postoperative [10, 11]. However it is difficult to separate the intraoperative injuries which were missed and identified in the postoperative period. The surgeon should be attentive for patient symptoms that cannot be explained by physical examination or routine studies and should be quick to investigate further. CT scans have been shown to identify a diagnosis in patients with unexplained pain, fever, or laboratory abnormalities following reconstructive surgery [23]. Documented postoperative complications of robotic ureteral reconstructive surgery include prolonged ileus, ureteral anastomotic leak, urinary retention, and port site erythema [20, 24].

#### Ureterolysis

In two studies of robotic ureterolysis involving a total of 22 procedures one perioperative ureteral leak was identified that was managed with prolonged Foley catheter drainage and ureteral stent placement, and one case of enterocutaneous fistula which required small bowel resection due to an unrecognized cautery injury [22, 25]. Robotic ureterolysis was unsuccessful in 7 of 40 patients (18%) and a second surgery required for persistent obstruction. Another study produced similar results with 14% requiring reintervention with ureteral reimplantation, robotic ureteroureterostomy, or laser endoureterotomy [14]. The use of intraperitonealization or omental wrapping can potentially prevent the risk of recurrent obstruction and need for additional interventions. Intraoperative ureteral stent placement may minimize the risk of postoperative obstruction or urinary leak [21].

#### Minimally invasive ureteral reimplantation

Robotic ureteral reimplantation has been shown to be safe in patients with minimal postoperative complications. Minor complications were common in a study of 16 patients where 75% had a postoperative complications. The majority included urinary tract infection, pneumonia, ileus, prolonged anastomotic healing, and prolonged abdominal pain. There was a small number of patients (13%) who required additional procedures [8]. Conversion to open approach is an uncommon intraoperative complication during robotic ureteral reimplantation or ureteroureterostomy, and was reported in two out of 16 patients (13%) in one study [26].

Anastomotic strictures following minimally invasive reimplantation was found in 10% in a study of 61 pediatric patients who underwent robotic extravesical reimplantation [27]. We use renal ultrasound as the first step in making the diagnosis, with excretory urography as confirmatory test. Placement of a ureteral stent is usually indicated to drain an obstructed system. If a stent is not possible, however, percutaneous nephrostomy tube placement may be necessary. Postoperative stricture can be managed initially conservatively with dilation, but if recurrent it may ultimately require additional surgeries to insure patient anastomosis. Transient obstruction secondary to edema is common postoperatively, and stenting for 4–6 weeks postoperatively is recommended. However, surgeons should be aware that after the stent is removed, patients may experience transient obstruction and may require stent replacement [28–30].

Urinary leak is a known postoperative complication and can be managed with maximal drainage, Foley catheter, and indwelling stent, and consideration of percutaneous drain placement. We suggest that a cystogram should be performed at the time of stent removal to confirm the absence of leak.

#### Minimally invasive ureteroureterostomy

The most common postoperative complications of robotic ureteroureterostomy include anastomotic stricture and urinary leakage. Although the published rates of postoperative complications for robotic ureteroureterostomy are low, a small series of eight patients were found to have a 25% rate of postoperative complication. All patients had radiographic and symptomatic success rates following surgery [14, 31, 32]. Obstructed retrocaval ureter have been repaired robotically by resecting diseased ureter and performing ureteroureterostomy without postoperative complications [6, 33, 34].

A significant amount of literature has shown that robotic ureteral surgery is safe for the treatment of upper urinary tract urothelial cell carcinoma. Proximal segmental ureteral surgery with ureteropelvic anastomosis and distal ureterectomy with reimplantation have both been performed for low-grade urothelial cell carcinoma without complications [35–38].

## New techniques in robotic reconstructive surgery

Complex proximal ureteral strictures can be challenging to manage. Although distal to mid-ureteral strictures can be successfully managed with ureteral reimplantation with psoas hitch or Boari flap, proximal ureteral strictures are often managed with ureteroureterostomy. However, when the afflicted ureteral segment is long, adequate mobilization to bridge the gap between healthy distal and proximal ureteral mucosa to allow for ureteroureterostomy may not be possible. Long or multifocal proximal ureteral strictures may require ileal substitution or autotransplantation of the kidney, options which are associated with significant potential morbidity from bowel and vascular complications.

The first use of oral mucosa grafts for ureteroplasty was in an animal model in 1984 [39]. Open buccal mucosa ureteroplasty has been used, but had not gained widespread use, because buccal mucosa is not often used by urologists [40–42]. However, for reconstructive urologists, buccal mucosa grafts have been a mainstay of treatment for ureteral strictures since it was first described in 1941 due to particular characteristics that make it ideal for the urinary tract [43, 44]. It has a pan-laminar vascular plexus ideal for engraftment and a thick nonkeratinized epithelium compatible with a wet environment. It is a graft material that has proven to be durable in the urinary tract without the risk of metabolic complications associated with use of bowel interposition [45].

## Indications and contraindications

Buccal ureteroplasty should be considered in patients with long or multifocal proximal ureteral strictures that are not amenable to ureteroureterostomy and that are being considered for autotransplantation or ileal ureter. Ureteral injury may be due to various etiologies such as trauma, iatrogenic injury from ureteroscopy or failed prior reconstructive surgery, or long standing nephrolithiasis. Renal scan should be performed to demonstrate obstruction, and adequate function in the affected kidney. Contraindications to buccal ureteroplasty include any oral diseases that prevent harvest of oral mucosa.

## Surgical steps

Following exposure of the ureter, we perform simultaneous ureteroscopy to allow for identification of the distal extent of the stricture. The use of dynamic ureteroscopy or intraureteral ICG can be used to confirm the extent of ureteral disease. Both the proximal and distal ends of the ureteral stricture are marked with a stay suture.

The graft site is prepared by making a ureterotomy lengthwise through the previously demarcated stricture segment until healthy-appearing normal-caliber ureter is reached proximally and distally. We have performed both anterior and posterior ureterotomies for buccal mucosa graft onlay. It has not yet been determined whether one approach is advantageous over the other.

The buccal mucosa graft (BMG) is prepared in the standard fashion and introduced into the abdomen through the assistant port and sutured onto the ureterotomy as an onlay graft (Figure 103.4). The edges are sutured in running fashion using 4-0 polyglactin suture. Dynamic ureteroscopy allows for visualization of the anastomosis from the ureteral lumen and early recognition of a misplaced of the suture to prevent improper ureter reconstruction. After the anastomosis is complete, a double-J ureteral stent is placed in retrograde fashion over a wire, and a Foley catheter is placed.

Graft survival depends on adequate apposition of the graft to its blood supply and we frequently use a flap of omentum because of its convenient location and ease of harvest. The omentum is prepared as previously described, and sutured to the omentum to maximize graft apposition to its new blood supply. If there is no omentum available, a flap of perirenal fat or the psoas muscle may be used to provide blood supply. As in previous reconstructive cases, we place a drain by the surgical site in case of urine leakage.

## Postoperative management

Patients undergoing buccal mucosa reconstruction require additional postoperative instructions. The use of antiseptic mouthwash protects the buccal mucosa harvest site, and we slowly advance the patient's diet. If a

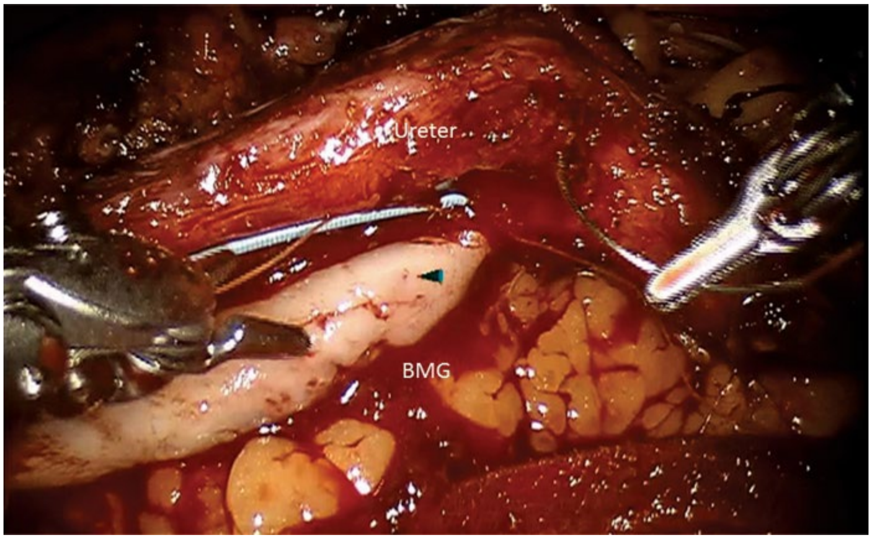

**Figure 103.4** Lengthwise ureterotomy performed, with stent visualized and graft prior to placement.

nephrostomy tube is in place, this is left in place and capped. As with all reconstructive cases, creatinine is checked prior to catheter removal and again prior to drain removal.

Six weeks after surgery, a retrograde or antegrade pyelogram is performed to confirm that there is no leak at the graft site prior to stent and nephrostomy tube removal. Subsequent surveillance includes renal ultrasound to evaluate for hydronephrosis after stent removal and diuretic renography at approximately three months to ensure the absence of obstruction.

### Follow-up

Our group has performed robotic buccal mucosal ureteroplasty on nine patients and there were no intraoperative complications noted [15]. The intraoperative techniques maneuvers to ensure a successful repair are the use of a well-vascularized tissue bolster, omental flap, or perirenal flap, to provide a vascular bed, use of intraoperative ureteroscopy to localize the stricture, ureteral instillation of ICG to identify well-vascularized ureteral tissue, and dynamic ureteroscopy during anastomosis to prevent back-walling the ureter during suture placement and to confirm a watertight anastomosis. From our early experience, we have recorded resolution of obstruction in 100% (mean 18 months). Early complications such as fever, which responded to antibiotics and antipyretics, and ileus, which was managed conservatively, have been noted [15].

## Conclusions

Robotic reconstruction has increased in popularity as surgeons are more comfortable with the robotic surgical system. Although only a small number of institutions have published their results, these studies have demonstrated the safety and efficacy of robotic ureteral reconstruction [4, 7, 8, 31]. These reports have also shown equivalent outcomes compared with open or pure laparoscopic approaches [10, 11]. The intraoperative and postoperative complications are generally low for robot-assisted ureteral reconstruction surgeries [12, 32, 35]. Inexperience with suturing is the most difficult aspect of these procedures and continues to be the challenge limiting the spread of this technology into the community. As robotic systems become more popular, and patients demand for this technology grows, robotic reconstruction will become more prominent throughout all urologic practices [3].

Unfortunately, the published reports on robotic reconstruction surgery are all retrospective case series [6, 7, 15, 31, 36, 41]. Well-powered, prospective, comparative trials are needed to assess the superiority of these techniques to traditional approaches. Another limitation of published reports is short follow-up; we need longer detailed reviews to evaluate whether radiologic and symptomatic success rates are sustained. Lastly, we need standardized definitions of complications for all institutions; this would help us to understand the actual morbidity of these surgeries and, more importantly, to create strategies to minimize complications.

# Laparoscopic Applications to Renal Calculus Disease

*Christopher S. Han & Sammy E. Elsamra*

*Division of Urology, Rutgers Robert Wood Johnson Medical School, New Brunswick, NJ, USA*

## Introduction

The advancements in extracorporeal shock-wave lithotripsy (ESWL), ureteroscopy (URS), and percutaneous nephrolithotomy (PCNL) have rendered open stone extraction for renal calculus disease obsolete. The use of open stone extraction has been limited, therefore, to more complex cases and only accounts for 2–5.4% of all stone cases [1, 2]. Nevertheless, open stone extraction is still indicated in complex cases with extremely large stones, renal malformations, special anatomic considerations, or in regions where ESWL, URS, or PCNL are not available [3]. The application of laparoscopic technology has allowed a minimally invasive surgical approach where open stone extraction is indicated (Table 104.1). With lower analgesia requirements, shorter hospital stay, and shorter convalescence [4, 5], laparoscopic stone extraction (LSE) is a better alternative than open stone extraction whenever expertise in laparoscopic techniques is available [6]. Utilization of laparoscopy has increased further with the adaptation of the da Vinci® robotic surgical system (Intuitive Surgical Inc., Sunnyvale, CA, USA), which offers unique advantages in maneuverability and intracorporeal suturing, allowing the surgeons to replicate nearly any open stone extraction laparoscopically. Although highly effective, LSE still remains as an alternative therapy in most cases due to its more invasiveness and higher complication risks. This chapter focuses on the applications and outcomes of LSE in renal calculus disease.

## Laparoscopic pyelolithotomy

In the modern era with the availabilities and advancements in the instruments for ESWL, URS, and PCNL, laparoscopic pyelolithotomy (LPL) is largely reserved for a complex renal anatomy, failed endourologic management, or simultaneous repair of ureteropelvic junction (UPJ) obstruction. It can also be considered in patients with very large stones and a large renal pelvis whereby whole extraction of such stones may result in higher stone-free rate (SFR) than PCNL. Furthermore, in some regions where the access to endourological instruments is limited, LSE can often be the most minimally invasive option available.

### Outcomes

Multiple studies have described both transperitoneal and retroperitoneal LPL for large renal pelvis stones ranging from 1.6 to 4 cm with high SFR (range 71–100%) (Table 104.2) [7–13]. Complication rates have been reported to range from 0% to 27% with open conversion rate up to 20%. Although earlier cases reported prolonged urinary leakage likely from pyelotomies that were not closed, later cases with intracorporeal suturing of the pyelotomy resulted in decrease in urinary leakage [8].

Initial comparison studies of both transperitoneal and retroperitoneal LPL to PCNL for a large renal pelvis stones have reported comparable SFRs (88% vs. 82%), estimated blood loss (EBL) (173 ml vs. 141 ml), complication rates (12% vs. 18%), and length of stay (LOS) (3.8 days vs. 3 days), respectively [14, 15]. The mean operative time, however, was significantly longer for LPL (142 minutes vs. 72 minutes). These results were later confirmed by a larger, randomized study [16]. In this series, no significant differences were seen on the intra- and postoperative parameters such as EBL, pain control, rate of blood transfusion, LOS, or SFR at three months (100% vs. 96%, respectively). The only difference was the mean operative time, which was significantly longer for the LPL group (130.6 minutes vs. 108.5 minutes, respectively).

The advancements in laparoscopic techniques, however, translated into more favorable outcomes with LPL in the more recent studies. Tefekli et al. reported a lower EBL and postoperative decrease in hemoglobin with LPL compared to the match-paired patients treated with PCNL [13]. Although not statistically significant, higher SFR (100% vs. 88.4%, respectively) was also seen with LPL. Recent randomized study and meta-analysis confirmed these results where shorter mean operative time and LOS was associated with PCNL whereas lower transfusion rates were seen with LPL [20, 22]. When compared to ESWL, LPL was also shown to have higher SFR, lower levels of postoperative pain, and a faster recuperation [23]. Some series also reported higher single-session SFR with LPL compared to ESWL and PCNL, especially with a larger stone burden [24]. Despite these more favorable contemporary series, the current combined evidences still suggest that LPL, although feasible, is only indicated under special considerations [12].

## Special consideration: renal pelvic stones with a concomitant UPJ obstruction

Renal pelvic stones with a concomitant UPJ obstruction is one of the most common situations where LPL is considered over other means of therapy. Approximately 20% of patients with UPJ obstruction harbor stone disease [25]. An extended pyelotomy, which can later be incorporated into the final pyeloplasty incision, is used to extract the pelvic stones with rigid graspers under direct laparoscopic vision [26]. A flexible endoscope (cystoscope preferred over ureteroscope) passed through one of the laparoscopic

**Table 104.1** Indications of the laparoscopic stone surgery.

ports, then through the pyelotomy, and into the renal collecting system can then be used to inspect and clear the calyces of remaining stones. In many series, SFRs of 75–90% can be achieved with up to 90% of patients showing no evidence of obstruction on follow-up diuretic renal scan [26, 27]. In a comparative study by Stein et al., concomitant LPL, compared to the laparoscopic pyeloplasty alone, was also shown to be both effective and safe with high SFR of 80% and comparable success rates of UPJ obstruction (93% vs. 100%, respectively) without a significant increase in morbidity or operative time (174 minutes vs. 170 minutes, respectively) [25]. Other intra- and post-operative parameters such as EBL, number of ports, and LOS were also similar between the two groups.

The application of robotics, especially with concurrent reconstruction, have also been reported, with advantages in improved maneuverability and visualization. Studies have reported additional mean operative time of 61.7 minutes for concomitant stone extraction without added complications or LOS during robot-assisted pyeloplasty (RAP) [21, 28]. One of the main concerns for any robotic application, however, is its added cost. These cost increases are mainly from the equipment depreciation, maintenance, and replacements, as well as longer operative time. Studies have shown that RAP may cost 1.7–2.7 times more than laparoscopic pyeloplasty [29, 30]. Its cost, however, can be mitigated by its shorter mean operative time (140 minutes for RAP vs. 235 minutes for laparoscopic pyeloplasty in one series) as well as lessened depreciation impact of the equipment in high-volume centers [30].

## Procedure

A preoperative evaluation with computed tomography (CT) should provide sufficient data regarding stone size, location of stone, and pertinent anatomy. A CT with contrast and delayed imaging may be of benefit when vascular abnormalities or other anatomic aberrancies exist (e.g. malrotated kidney). If a CT is not available, an intravenous pyelogram (IVP) can be considered.

Both transperitoneal and retroperitoneal approaches are feasible for LPL. The author's preference is the transperitoneal approach. After positioning the patient in the modified contralateral decubitus position with all pressure points well padded and the patient appropriately secured to the bed, the patient's abdomen and genitalia are prepped and draped in the usual sterile manner. A Foley catheter is then placed. Pneumoperitoneum is achieved with the surgeon's preferred method. A Veress needle or Hasson technique is utilized to establish pneumoperitoneum at either umbilical or left upper quadrant (Palmer's point) areas. Once pneumoperitoneum is established with 15 mmHg of $CO_2$ pressure, three ports are placed in a triangular configuration, with a 12 mm port at the umbilicus, a 12 mm port in the ipsilateral lower quadrant and a subxiphoid 5 mm port (may be upsized to a 12 mm port) (Figure 104.1). An additional 5 mm incision with or without port under the xyphoid process can be utilized for a self-locking grasper for liver retraction during the right-sided procedure if necessary. For an obese patient, the ports are displaced laterally and cephalad.

Once ports are placed, the table is rotated toward the contralateral direction such that the camera port is flat to the horizon. Using a 30° down scope, the abdominal contents are inspected and the white line of Toldt is incised to allow for medial reflection of the colon. The ureter is then identified over the psoas muscle (running parallel to the gonadal vessels) and traced up to the renal pelvis. Stones in renal pelvis are generally easily identified due to their bulge. If the identification is difficult due to surrounding inflammation and/or adhesions, more thorough dissection to expose the renal pelvis may be necessary. Care must be taken to avoid inadvertent injury to the ureter or renal pelvis in case of tissue friability which is often present. Laparoscopic ultrasound or on-table fluoroscopy can be utilized to locate the stone in the pelvis or any fragments in the calyces.

A pre-positioned ureteral catheter may facilitate identification of the ureter and renal pelvis. This can also serve to test for watertight closure of pelvis and to place a ureteral stent in a retrograde manner toward the end of the case. Placement of ureteral catheter should be performed at the beginning of the case, either before the laparoscopic portion or, alternatively, during, with a flexible cystoscope by the assistant surgeon while the patient is in the modified flank position and undergoing the laparoscopic portion of the case. Alternatively a ureteral

stent can be passed in the antegrade fashion before closure of the pyelotomy.

Pyelotomy should be made and extended with laparoscopic scissors in a longitudinal fashion using a curvilinear incision (Figure 104.2a). The surgeon must plan the size and direction of the pyelotomy based on the size and location of the stone, the renal pelvis anatomy, and whether or not it will be incorporated into a pyeloplasty. A flexible cystoscope, and if necessary a flexible ureteroscope, may be passed through one of the 12 mm ports into the pyelotomy to inspect the renal pelvis and all calyces for stone (Figure 104.3). Stone basket extraction may be performed when necessary. Pressure irrigation to 300 mmHg with normal saline is used to create a turbulent flow inside the pelvis for adequate hydrodistention for exploration. The mucosal adhesions to the stones can be dissected off using a right-angle dissector [31]. An endoscopic retrieval bag may be used to minimize the risk of intra-abdominal stone loss and to facilitate the extraction of multiple and/or small stones (Figure 104.2b). A double pigtail ureteral stent is left in place; either placed over a wire inserted through the previously placed ureteral catheter or introduced over a wire in the antegrade direction through the pyelotomy (Figure 104.2c). The pyelotomy is then closed with a 3-0 absorbable suture (e.g. polyglactin) (Figure 104.2d). A closed suction drain is placed in proximity to the pyelotomy. The abdominal fascia on the 12 mm port sites are closed with figure-of-eight 2-0 polyglactin sutures, and the skin is closed either with running subcuticular closure or staples.

In the retroperitoneal LPL, the patient is placed in the full-flank position and secured to the bed with all pressure points well padded. A 2 cm incision is made below the tip of the 12th rib on the posterior axillary line. The retroperitoneal space is then bluntly dilated with the index finger. A 12 mm balloon trocar system is then used to further develop the retroperitoneal cavity. Pneumoretroperitoneum is created with insufflation pressure of 15 mmHg. Under direct visualization, the working trocars (12 mm and 5 mm) are placed four fingerbreadths away from the camera port directly above (12 mm port) and below (5 mm port) it. In an obese or tall patient, the trocar placements should be displaced superiorly for optimal working environment. A fourth trocar can be placed after further reflection of the peritoneum anteriorly if needed. The renal pelvis should be visualized first in the hilum. The rest of the procedure is carried out similar to the transperitoneal LPL.

The retroperitoneal approach has several theoretical advantages over the transperitoneal approach. It is thought to have decreased risks of visceral injury from the trocar placement as well as from manipulation during the procedure. Less irritation of the intestine and peritoneum from urine in the retroperitoneal space is another theoretical advantage. The transperitoneal approach, however, provides more familiar anatomy to most surgeons with larger working space. Balloon dissection to create the retroperitoneal space is also not necessary in this approach. As discussed above, both approaches are considered safe and effective during LPL, and it is the surgeon's preference and comfort level that should dictate the method of choice.

## Laparoscopic anatrophic nephrolithotomy

Laparoscopic anatrophic nephrolithotomy (LAN) is mostly reserved for large staghorn calculi that have failed or may require multiple endourological treatments with PCNL and/or ESWL [32]. SFR is particularly important in staghorn stones, with attendant high risks of renal function deterioration and recurrence rates [33]. Anatrophic nephrolithotomy can be advantageous in achieving high SFR with less cost over multiple endourological procedures required to attain a similar, if not less successful, result [34]. Esen et al. compared open anatrophic nephrolithotomy (OAN) with ESWL monotherapy and ESWL with PCNL combined therapy in patients with staghorn calculi [35]. SFRs of 80%, 32%, and 50% were achieved with OAN, ESWL monotherapy, and ESWL–PCNL combination therapy, respectively. Although higher EBL was noted with OAN, the benefits of OAN with SFR was substantial.

### Outcomes

LAN is a minimally invasive alternative to OAN. In 2003, Kaouk et al. were the first to describe LAN in a porcine model [36]. This study, which utilized the techniques of OAN with a mean warm ischemia time of 30 minutes, showed the feasibility of laparoscopic application for a large staghorn stones. This was quickly followed by Deger et al. describing the first LAN in patients with complete staghorn stone via transperitoneal approach [37]. Cold ischemia with ice slush was used, with mean ischemia time of 45 minutes. The collecting system was closed with an absorbable running suture. No complications were reported, and the patient's follow-up IVP and renal scan showed resolution of obstruction and improvement in renal function, respectively. Since then, more contemporary series utilizing warm ischemia have reported similar efficacy and safety of both transperitoneal and retroperitoneal LAN in treating staghorn stones [38–40]. In over 40 patients with mean stone sizes ranging from 4.5 to 6.5 cm, warm ischemia time and operative time ranged from 29 to 35 minutes and 120 to

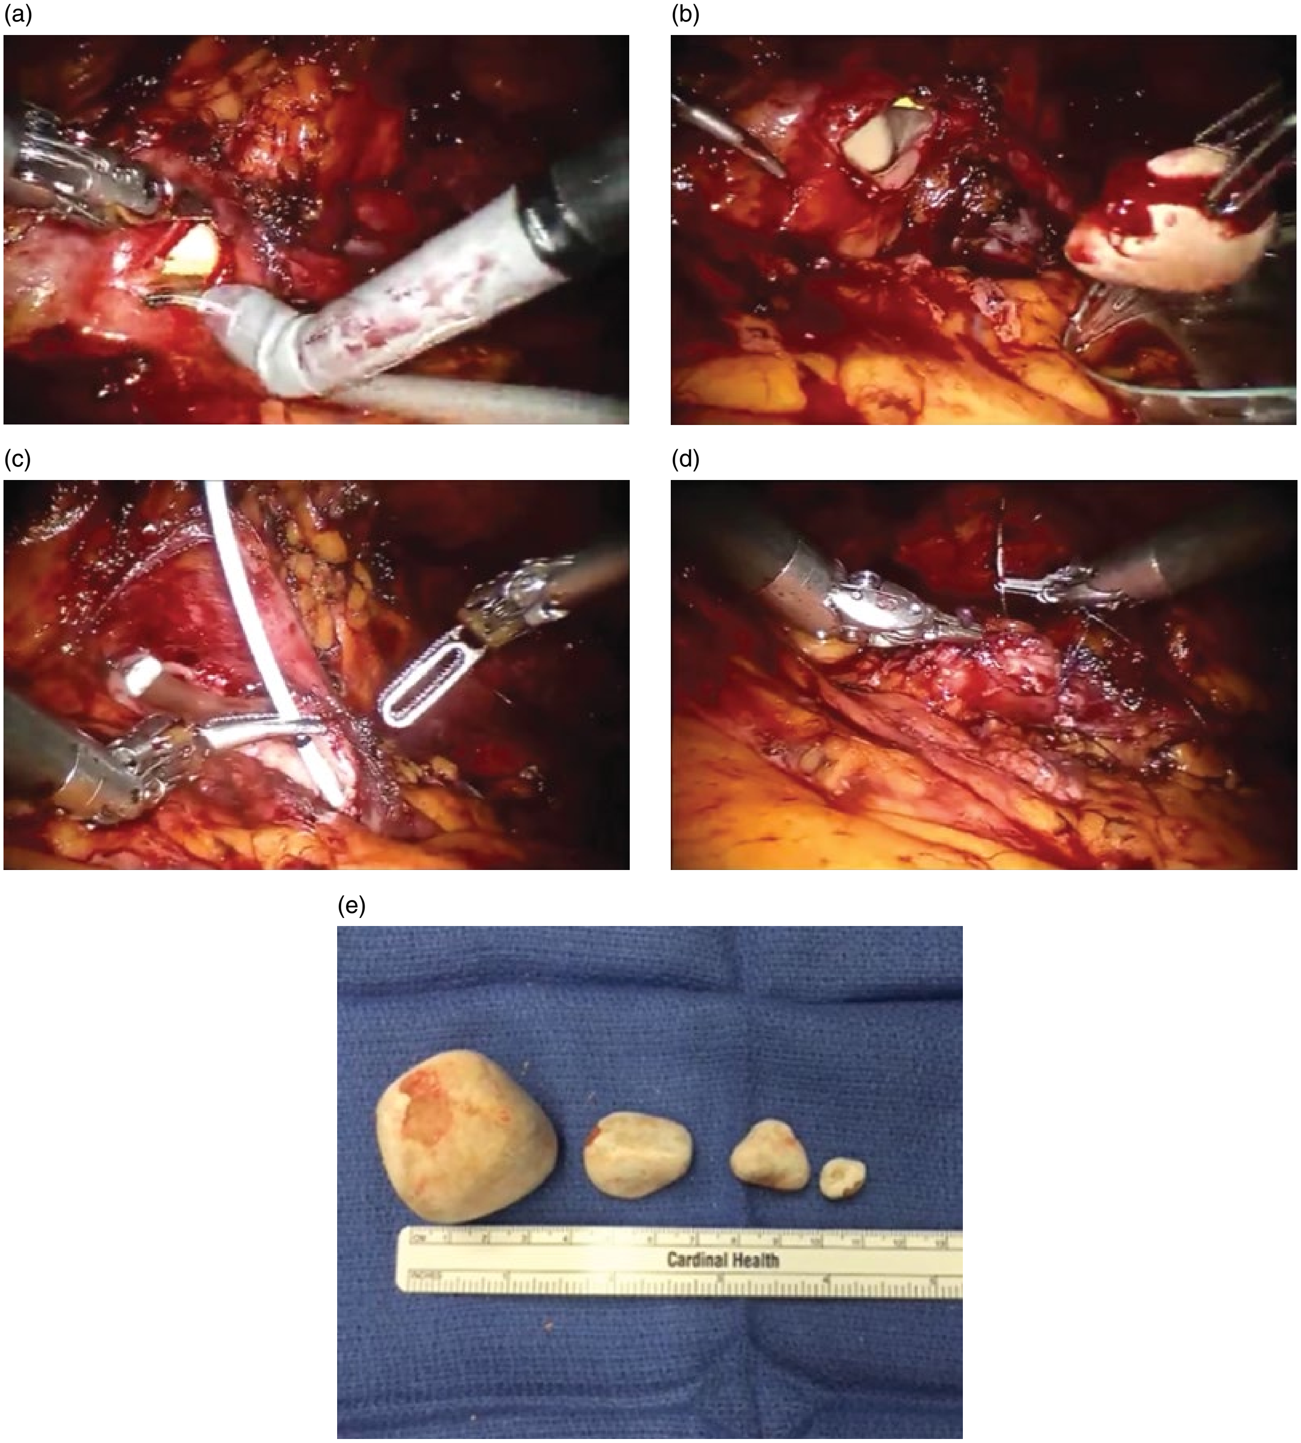

**Figure 104.2** Robot-assisted laparoscopic pyelolithotomy. (a) Pyelotomy for stone retrieval. (b) Stone retrieval with endoscopic retrieval bag. (c) Antegrade ureteral double pigtail ureteral stent placement. (d) Closure of pyelotomy with running suture. (e) Retrieved renal stones.

225 minutes, respectively. The reported SFRs ranged from 88 to 91% with the majority of residual stones successfully managed with postoperative ESWL. Postoperative IVP confirmed significant improvements in obstruction and functional corresponding renal unit in all studies. Mean LOS of 3.5 days with minimal changes on serum creatinine values were also reported [41]. Despite its effectiveness, LAN is still considered an invasive procedure with one of the series reporting a rather high transfusion rate of 24% with 20% rate of Clavien

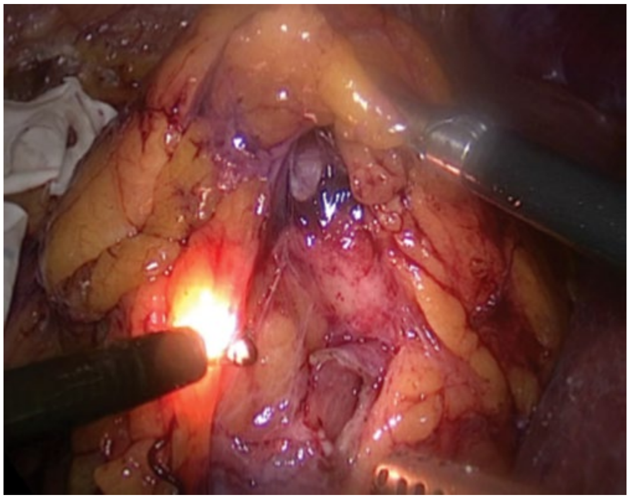

**Figure 104.3** Use of flexible endoscope for stone exploration during laparoscopic pyelolithotomy. *Source:* Gandhi HR, Thomas A, Nair B et al. Laparoscopic pyelolithotomy: an emerging tool for complex staghorn nephrolithiasis in high-risk patients. *Arab J Urol* 2015;13(2):141. Reproduced with permission of Elsevier.

grade III or higher complications including nephrectomy [39]. LAN should, therefore, be limited to expert laparoscopic surgeons.

Another concern during LAN is the inevitable ischemia with no known long-term functional outcome following LAN. The proficiency of laparoscopic suturing technique as well as patient selection are, therefore, crucial in the success of LAN. Extrapolating results from partial nephrectomy, the reported warm ischemia times for LAN are acceptable for long-term preservation of renal function [42]. Those with multiple particles in different calyces, rather than a single large staghorn stone, may have increased warm ischemia times making them less suitable for LAN. Robotic applications for LAN have also been reported with cold and warm ischemia times, SFRs, and mean operative times comparable to those for nonrobotic LAN [43, 44].

## Special consideration: calyceal diverticular stone

Laparoscopic diverticulectomy with simultaneous stone removal is another relative indication for a laparoscopic nephrolithotomy (LNL). Although rarely indicated or performed, the laparoscopic approach is a suitable option for a previously failed endourological intervention, anteriorly located diverticula which are usually difficult to access percutaneously, or large stone burden with narrow diverticular neck which precludes management with ESWL or URS [45]. The incidence of calculi within calyceal diverticula has been reported to be between 10% and 50% [46]. Multiple series with laparoscopic applications for calyceal diverticula with concomitant stones have been reported with high efficacy and safety (Table 104.3) [47–52]. Stone localization is usually achieved without much difficulty as the overlying cortex in such cases is generally thin and is either bulging with the stone or depressed because of scarring. Palpation with instrument, aspiration, indigo carmine injection, fluoroscopy, or ultrasonography have been utilized for locating the stone-filled diverticula. A "cut to the light" technique is also useful where endoscopic light from the flexible ureteroscope introduced at the obstructed calyx localizes the location of the diverticula (Figure 104.4a) [53].

**Table 104.3** Laparoscopic calyceal diverticulectomy with simultaneous stone removal.

| | |
|---|---|
| Stone size | 3–45 mm [48–52] |
| Diverticulum size | 1.3–4.5 cm [48–52] |
| Stone-free rate | 100% [48–52] |
| Diverticulum recurrence rate | 8.3% [48–52] |
| Mean operative time | 80–215 min [48–52] |
| Estimated blood loss | 0–150 ml [48, 49] |
| Conversion rate | 0% [48–52] |
| Complication rate | 8.3% [48–52] |
| Mean length of drain | 1–4 days [48–51] |
| Mean length of stay | 1–4 days [48–52] |

Once the stone is removed, diverticula are generally managed with fulguration [11], argon beam coagulator [52], closure of the cavity with perirenal fat [49] or synthetic glue [50], or suturing of the diverticular neck [48]. The presence of diverticula with a thick rim of renal parenchyma, however, is a relative contraindication for the laparoscopic approach. In such cases, difficulties with the localization of diverticula as well as the control of bleeding from the nephrolithotomy incision are expected. LNL in such cases is still feasible but the technique would then resemble a partial nephrectomy for an endophytic tumor rather than a stone extraction. Although ultrasonography with color Doppler may aid in localization of the diverticula while avoiding major vessels [52], Gerota's fascia is opened, making spontaneous compression unlikely for hemostasis (unlike the percutaneous procedures). Preoperative review of imaging studies is, therefore, paramount as these patients may need to be counseled for renorrhaphy following diverticulectomy and stone removal.

## Procedure

Patient positioning and port placement are similar to those used for transperitoneal approach described above. The renal hilum is skeletonized and the kidney is mobilized completely. A laparoscopic ultrasound is performed

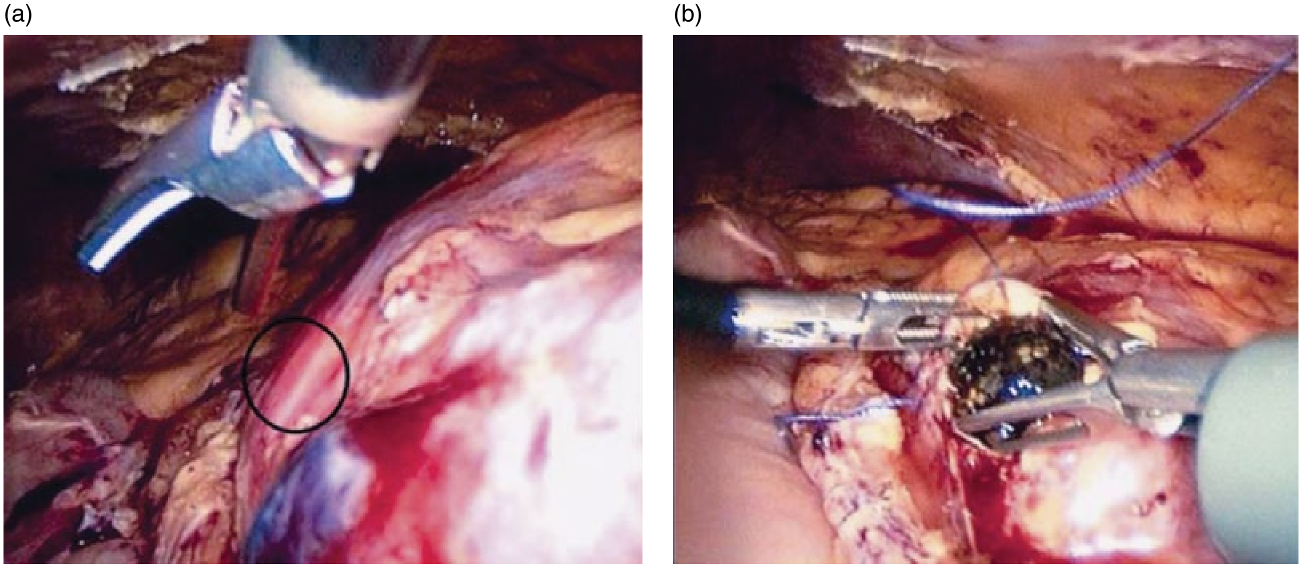

**Figure 104.4** Laparoscopic management of calyceal diverticular stone. (a) Endoscopic light transilluminates the location of the obstructed upper pole calyx (area inside circle). (b) The kidney is incised over the lighted parenchyma and the stone removed laparoscopically. *Source:* Nadu A, Schatloff O, Morag R et al. Laparoscopic surgery for renal stones: is it indicated in the modern endourology era. *Int Braz J Urol* 2009;35(1):9–17. Reproduced with permission of Oscar Schatloff.

to assess location of stone burden. Laparoscopic bulldog clamps are applied to the renal hilum. The author prefers two bulldogs placed on the renal artery and one bulldog on the renal vein (Figure 104.5a). A longitudinal incision through the renal parenchyma at Brodel's line is created (Figure 104.5b). This is the theoretically avascular line separating the anterior and posterior segmental arterial distribution and is typically located at one-third of thickness from the anterior aspect. Incision is continued with laparoscopic scissors until calyces are entered and stone is identified. A laparoscopic scissor or scalpel can be used to extend the incision into the collecting system to allow for full identification and extraction of the stone. Once all stone is evacuated and placed into the endoscopic retrieval bag, the collecting system is reapproximated utilizing a running 3-0 polyglactin suture and a capsular renorrhaphy is performed using 2-0 polyglactin or V-Loc™ (Covidien/Medtronic, Minneapolis, MN, USA) suture (typically with a sliding Hem-o-lok® (Teleflex Medical, Research Triangle Park, NC, USA) technique) (Figure 104.5c). Next, the bulldog clamps are removed, the kidney is assessed for reperfusion and hemostasis, and a drain is placed. The endoscopic retrieval bag is extracted and port sites are closed.

## Laparoscopic ureterolithotomy

Laparoscopic ureterolithotomy (LUL) is an alternative option for a large impacted ureteral stone, following a failure of ESWL or URS therapies, for a socioeconomic necessity where stone clearance with a single treatment session is required, or where appropriate technological instruments are lacking. Since the first description of LUL by Wickham in 1979 [54], multiple studies have reported its efficacy and safety [8, 55–60].

### Outcomes

LUL duplicates open ureterolithotomy with the advantage that it is minimally invasive. Both transperitoneal and retroperitoneal LUL were compared with open ureterolithotomy, and lower analgesia requirements, shorter LOS (3–3.3 days vs. 4.8–8 days), and shorter convalescence (1.8 weeks vs. 3.1 weeks) were reported with LUL [55, 56]. No significant differences were seen in the mean operative time (108.8 minutes vs. 98.8 minutes, respectively) and EBL (58.5 ml vs. 50.5 ml, respectively). One study reported 12% conversions due to stone migration into the kidney, inability to locate the stones due to extensive periureteric fibrosis, or vascular injury [56]. These conversions, however, occurred early in the series with no conversions reported in their later cases. Although this may raise a concern for a steep learning curve, Fan et al. reported that such curve is rather shallow with improved complication rates and operative time after first 20 cases [57].

The SFRs in most series with both transperitoneal and retroperitoneal LUL approached 100% with low conversion rates [8, 55–60]. In the largest LUL series by Simforoosh et al. with 123 patients, an SFR of 96.7% was reported with calculi ranging from 1 to 5.6 cm. The mean

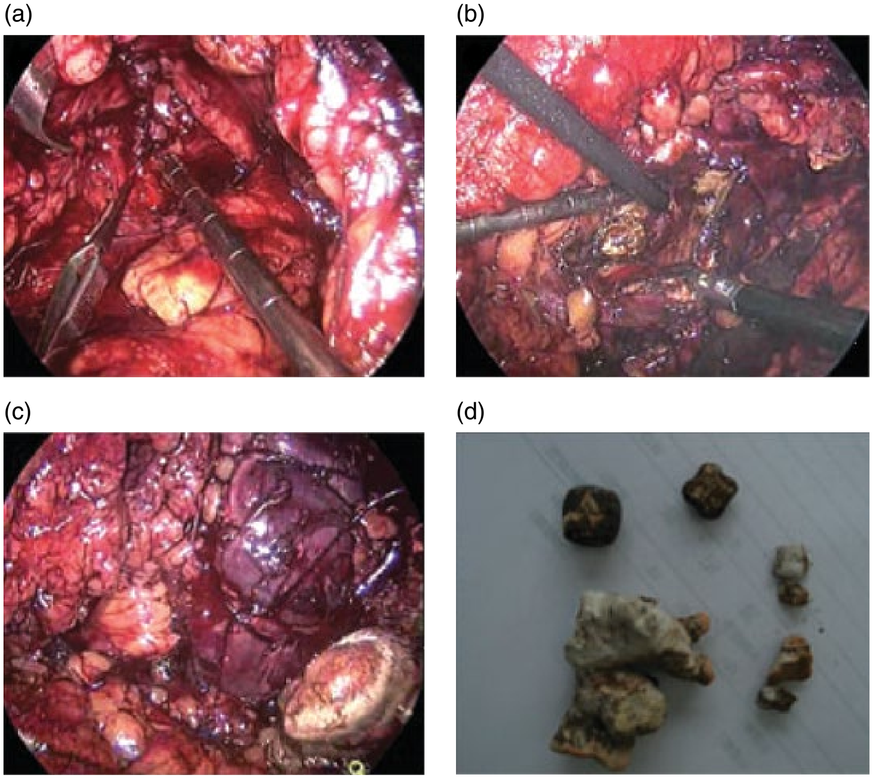

**Figure 104.5** Laparoscopic anatrophic nephrolithotomy. (a) Renal artery clamped temporarily with a bulldog clamp. (b) Nephrotomy incision. (c) Nephrotomy closure with running sutures. (d) The staghorn stones extracted. *Source:* Zhou L, Zuan, Q, Wu B et al. Retroperitoneal laparoscopic anatrophic nephrolithotomy for large staghorn calculi. *Int J Urol* 2010. Reproduced with permission of John Wiley & Sons.

operative time was 143.2 minutes [58]. A minor complication rate of 11.4% was reported, including an open conversion due to migration of the calculus. Interestingly, multiple studies reported a significant difference in the mean operative time between the transperitoneal and retroperitoneal approaches (137.3 minutes vs. 171.3 minutes in one study, respectively) without significant differences in EBL and transfusion requirements [58, 60]. In a recent prospective study, a significantly lower SFR (72% vs. 100%) with retroperitoneal approach was also reported [61]. Although the retroperitoneal approach was associated with shorter time to oral intake (15 vs. 21 hours), longer mean operative times with higher open conversion rates (27.3% vs. 0%) were reported as well. Although no randomized studies are available comparing the two approaches, these data suggest that surgeons still early in their learning curve in LSE should perform LUL using a transperitoneal approach. The application of robotics in LUL has also been reported with high SFRs and decreased operative times, likely due to its improved control, dexterity, and precision [62, 63].

The comparison studies of LUL with URS, PCNL, or ESWL for ureteral stones have shown favorable SFRs for LUL, reaching up to 100% [64–66]. Although longer mean operative times and LOS were observed with LUL when compared to URS (with no increased risk of complication), comparable mean operative times, EBL, urinary leakage rates, and LOS were seen compared to PCNL. LUL, however, has significantly higher SFRs compared to ESWL (93.3% vs. 35.7% in one study). Although these recent reports showing higher SFRs with LUL could represent advancements in laparoscopic skills, flexible ureteroscopes which could aid in stone clearance with stone migration into the renal pelvis were not utilized in some of the studies. The stone up-migration is usually significantly higher with URS.

In LUL, the most common early postoperative complication is urine leak (0–20%) followed by stricture formation (1.4–5.2% risks) [8, 56, 57, 65, 67–70]. Controversy about whether to close the ureterotomy and whether to place a ureteral stent, therefore, still exists. No significant differences have been reported between closing the ureterotomy [8, 69] and leaving it open [67, 68], as well as stenting and no-stenting after LUL [71]. The duration of urine leakage is probably longer, however, if the ureterotomy is neither closed nor stented [70]. The most serious late complication of LUL is ureteral stricture formation, which occurs at an incidence of up to 20% [12]. The common etiologies for stricture development are periureteritis, urinary leak, use of diathermy to incise the ureter, and stone impaction.

One potential application of LUL is in cases where there has been prolonged impaction of a large stone within the ureter associated with significant periureteral fibrosis and adherence of stone to the ureteral mucosa. In such cases, endoscopic management may result in high ureteral stricture rates [71, 72] and it may be best to perform a laparoscopic or robotic segmental ureterectomy with primary uretero-ureterostomy, if the defect is not prohibitively long.

### Procedure

Preoperative evaluation, patient positioning, peritoneal access, and port placements are similar to those of LPL and LAN. The ureter is located on top of the psoas muscle after the mobilization of colon. The stone is then identified either with palpation or visual contact. Laparoscopic ultrasound or on-table fluoroscopy can aid in its localization as well. Once the stone is localized, the ureter is occluded both proximal and distal to the stone with the vessel loops to minimize the risk of stone migration. A longitudinal incision is made over the stone with a laparoscopic scissor to remove the stone with the stone grasper. Care should be taken not to use any thermal energy on the ureter to minimize the risk of ureteral stricture disease. An endoscopic retrieval bag is used to remove the stone from the abdomen. Different methods have been described for the ureterotomy management. It is perhaps best to both close the ureterotomy with 4-0 polyglactin interrupted sutures and place the double-J ureteral stent to minimize the risk and duration of urine leak. However, if the ureter is chronically inflamed, edematous, and friable due to infection or prolonged impaction, the ureter should only be stented and not sutured to decrease the risk of prolonged leakage [70]. A drain is placed as well and removed in postoperative day 1 if urine leak is not suspected. The ureteral stent is removed in one to two weeks in the office.

The retroperitoneal approach is also feasible for proximal and midureteral stones. The port placements and retroperitoneal access are similar to those of LPL or LAN. The distal ureteral stones, however, are difficult to reach retroperitoneally, and transperitoneal approach is recommended. The fascia and skin are closed in a similar fashion as in LPL or LAN.

## Laparoscopic partial or simple nephrectomy

Laparoscopic partial or simple nephrectomies are considered when the function of the entire kidney or a renal moiety in a duplex system is lost due to renal calculus diseases [10, 11, 70, 73–76]. Overall SFRs approach 86–100%, but the prolonged inflammation and/or infection in the renal or the perirenal tissues usually associated with these conditions make the procedures more difficult, with reported open conversion rates up to 14%. A history of multiple prior endourological interventions is also often encountered in these patients, further obscuring the tissue planes. If excess adhesions are suspected or encountered, the hilum should first be approached outside of Gerota's fascia, which leads to safe dissection with minimal bleeding [10]. The procedural basics of laparoscopic partial and simple nephrectomies largely duplicate those of the laparoscopic oncologic counterparts and are discussed in detail elsewhere in the text.

## Anatomic anomaly and laparoscopically assisted endourology

Renal anomalies such as horseshoe kidney, ectopic kidney (most commonly in the pelvis), crossed fused ectopic kidney, transplant kidney, or urinary diversions introduce challenges to the urologist due to less effective endourological interventions compared to those without the anomalies and increased risk of complications associated with the interventions. These patients are also at increased risk of stone disease from relative urinary stasis. Although PCNL, unlike URS and ESWL, has been shown to be as effective in patients with renal anomalies as in those with normal anatomy with stones [77–81], difficulties in gaining access due to increased skin-to-stone distance and/or abnormal location raises concern for suboptimal access or complications including bowel or vascular injuries. Puncture through suboptimal structures (e.g. greater sciatic foramen, transhepatic, and transiliac) have been described in the past [82–84]. Laparoscopic application in renal anomalies, therefore, could be considered with its advantages of direct visualization and high SFRs.

The evidence relating to LSE in renal anomaly is scant, but excellent outcomes have been reported in small series. The reported SFR ranges from 91% to 100%, with mean operative time, EBL, and LOS comparable to those with normal anatomy [85–87]. Due to anatomic variances associated with renal anomaly, preoperative ureteral catheter or stent placement may aid in localization and repair in these cases.

As flexible endoscopes are utilized during LSE for stone fragment localization and/or retrieval, laparoscopy can be combined with endourological procedures, especially with PCNL, to aid in safe and successful access in the patients with renal anomalies. Multiple studies have reported high SFRs and low complications [88–91]. Patients are usually positioned in the Trendelenburg position to move the bowel away from the area of interest, and the kidney is punctured under direct visualization with continued displacements of bowel or the adjacent structures to avoid injury. Both transperitoneal and extraperitoneal approaches have been described with SFRs up to 100% and operative times and complication rates comparable to those of standard PCNL [90, 91]. Suturing of the nephrostomy site with ureteral stent placement under laparoscopic guidance, which eliminated the need for a nephrostomy tube, has also been described [91].

### Common limitations

One of the challenges of LSE is locating the original stone, especially in the ureter, as well as the small residual stones/fragments. Although the large stone burden prompting LSE often causes enough of a bulge or depression of the overlying tissue aiding in its identification, inflammation of the surrounding tissue can make it difficult during laparoscopy where tactile feedback is suboptimal. Lost stone in the abdomen during LSE is another challenge which may prompt open conversion if the stone is too large, too numerous, or infected. Fluoroscopy can aid in this process if it is available during LSE. Introduction of a C arm, however, is cumbersome during LSE. The image quality is also suboptimal due to the insufflation and free fluids in the abdomen during LSE. Intraoperative ultrasound has been utilized, but the difficulty still remains in locating the small residual stones.

Combining the flexible cystoscope with LSE is also challenging due to the crowded operative field with the instruments and limited ability to achieve enough irrigation pressure when the incision is made in the urinary system. The urine and free fluid introduced into the abdomen from the irrigation fluid are also a concern, as these may irritate the bowel, causing ileus. A retroperitoneal approach can theoretically minimize this problem if the surgeon is familiar with the anatomy. Efforts should be made to aspirate as much free fluid as possible at the end of the case by placing the patient in a Trendelenburg position to allow the fluid to accumulate under the diaphragm for easier aspiration during laparoscopy. Furthermore, many of the procedures described above for LSE require significant mobilization of the kidney within Gerota's fascia which may reduce the ability of this layer to provide protection against urinary leakage and hemorrhage.

## Conclusions

Although LSE is a less invasive alternative to open stone extraction with favorable safety and efficacy, the classical endourologic procedures should still remain the gold standard in the treatment of renal stone diseases. LSE is a good treatment modality, however, that is available to the urologist when other endourological options are suboptimal or have failed.

## Laparoscopic treatment of renal cysts

### Introduction

Renal cysts are localized fluid-containing formations separated from the renal parenchyma by a pseudocapsule and are considered the most common incidental findings of the kidney. Approximately 70–80% are solitary, unilateral, and cortical, but they can potentially develop in every part of the kidney and appear as multiple or bilateral cysts, with a variable dimension from few millimeters to more than 10 cm. In about a quarter of total cases, mostly in young patients, they grow bigger over time. A specific rate of growth has never been clarified, but in general they develop through as much as space as they can find. Cysts never communicate directly with the urinary excretory system and their internal surface is never covered by urothelium [1–4].

Renal cysts are common findings in routine imaging examinations and their incidence increases with patients' age. Between birth and 20 years old, the occurrence of new cysts is very rare, but thereafter it begins to increase in incidence, with a male-to-female ratio of about 2:1 in some series. About one-third of the population over the age of 50 has an asymptomatic renal cyst.

Occasionally they can become symptomatic, mainly due to compression of renal sinus or of the ureter, which can cause acute pain manifesting as renal colic, infection, or urinary obstruction due to urinary stasis. In addition, hemorrhagic or malignant degeneration of the cyst is also possible [5, 6].

Some congenital diseases, such as autosomal dominant polycystic kidney disease (ADPKD), von Hippel–Lindau (VHL) syndrome, and tuberous sclerosis disease, are commonly associated with the presence of multiple characteristic cysts, often with a tendency toward malignant degeneration [7].

The application of laparoscopic surgery in renal cyst management sometimes has a proper rationale. This chapter covers the role of laparoscopy in simple renal cyst exploration and decortication. Complex cyst management is discussed elsewhere.

### Radiologic findings

Simple cysts are classically cortical with an exophytic growth pattern and can alter the renal profile. They can present with a circular or oval shape and are filled with a homogeneous fluid with a radiodensity comparable to water, usually ranging from −10 to 20 Hounsfield units (HU) on computed tomography (CT) imaging. Nearly 6% of simple cysts are complicated by hemorrhage. A hemorrhagic cyst may progress from blood liquefaction subsequent to a local trauma involving the kidney parenchyma, or a hemorrhage may be a complication of a simple cyst developing due to expansion or bleeding diathesis. The CT attenuation value of an acute hemorrhagic cyst ranges from 70 to 90 HU, but it falls as blood liquefies and organizes. The evolution of a hemorrhagic cyst includes development of calcification in a central or peripheral configuration with subsequent thickening and alteration of morphology, becoming multilocular as consequence of septae expansion, acquiring some features of a complex cyst. Infection is an additional potential complication of simple cysts. The walls of infected cysts are often markedly thickened with an increased HU attenuation, without contrast enhancement.

In patients with history of ADPKD, VHL, or tuberous sclerosis, specific radiologic screening is compulsory because of the high risk of cyst development and malignant degeneration.

Renal cysts are generally categorized using the radiological system formulated by Bosniak [8], who classified them based on their morphological appearance and contrast enhancement on CT abdominal scan. Type I cysts have a flat muscle wall, and are filled with clear amber liquid; type II cysts, also benign, have minimal septation and small amount of calcification; type III cysts have a large number of septae with thick cyst walls; type IV cysts have irregular walls, with calcifications or hemorrhagic areas and sometimes a clear solid mass inside the cyst, suggesting a carcinoma [9].

Although the original Bosniak classification of a stage I renal cyst does not include their dimensions, an update published in 2005 notes a diameter of ≥3 cm as requiring follow-up and employs this size among the main variables used to discriminate between a stage II or IIF cyst [10].

Another revision of this classification system was suggested in 2004 by Israel et al., with a direct comparison between CT and magnetic resonance imaging (MRI) findings [11]. Analyzing a cohort of 59 patients with an overall number of 69 renal masses, they validated Bosniak classification using MRI images and demonstrated that MRI is better than CT in determining cyst morphology, septations, calcifications, or contrast enhancement. These findings suggest that MRI imaging may be an alternative imaging technique to CT, especially for younger patients who will undergo repeated examinations. Moreover, clinicians should select the same imaging methodology for each patient, as a switch from CT to MRI imaging could give the erroneous appearance of cyst evolution.

A full classification of renal cysts according to Bosniak criteria is presented in Table 105.1.

## Indications and contraindications to laparoscopic treatment

### Simple renal cysts (Bosniak I and II)

Most simple cysts are totally asymptomatic and will never demand active treatment.

Although surgical treatment of Bosniak I and IIF renal cysts is not normally needed, patients may present with important symptoms such as pain, infection, and urinary obstruction. In fact, simple cysts can in some cases grow enough to result in compression or rupture of collecting systems, likely related to a trauma [12]. Moreover, cystic fluid can become infected, needing surgical treatment. As a simple cyst grows, it may rarely result in systemic hypertension or impairment of renal function by causing tubular obstruction or local ischemia [13].

Nowadays, percutaneous drainage and sclerotherapy are the most frequent first-line treatments for symptomatic simple renal cysts [14]. Laparoscopic treatment is accomplished for patients in whom conservative procedures have failed or are contraindicated (obese patients, bleeding disorders, complex location of the cyst, etc.). Another indication for first-line laparoscopic treatment is the presence of concomitant pathologies of the ipsilateral kidney or upper urinary tract which necessitate surgical treatment (i.e. pielolithotomy, pyeloplasty, simple tumor enucleation, or partial nephrectomy) [15].

Marsupialization, decortication, and unroofing are the three main techniques described for simple renal cyst laparoscopic treatment. The patient should be preoperatively informed that if malignancy is suspected intraoperatively, the treatment can vary toward a more radical surgical excision [16].

### Complex renal cysts (Bosniak III and IV)

Diagnosis of simple cysts is often incidental in the absence of specific symptoms. A specific meta-analysis found that Bosniak class II, III, and IV cysts are associated with the risk of 24, 41, and 90% of malignancy, respectively [17].

Some authors have described the possibility of cyst aspiration to rule out the presence of malignant cells, even if this practice is strongly not recommended because of the high risk of tumor seeding and the possibility of a false-negative result [18]. Conservative management is never recommended for lesions Bosniak III–IV because of the high suspicion of cancer and, as for percutaneous aspiration, preoperative biopsy is not indicated.

Finally, in view of the findings that approximately 40–60% of class III and 85–100% of class IV cysts prove to be malignant, laparoscopic simple enucleation, partial or radical nephrectomy is always demanded [1, 2].

The main limit for the laparoscopic approach is represented by intraparenchymal cysts, treatment of which can be difficult because of the risk of significant bleeding and injury to the collecting system. In these situations, an open surgical approach should be considered.

## Laparoscopic treatment

Laparoscopic treatment of simple renal cysts represents an ideal approach as it minimizes surgical morbidity potentially related to lombotomic incision performed for conventional open procedure. Before deciding on laparoscopic treatment for a patient with a simple renal cyst, percutaneous puncture could be performed under ultrasound guidance with aspiration of cystic liquid. This would demonstrate a cause-and-effect relationship between the cyst itself and symptoms reported by the patient [19].

### Preoperative evaluation and patient preparation

Even if standard abdominal ultrasound study is used to diagnose simple renal cysts, a detailed preoperative

| Renal cysts<br>Bosniak categories | CT | MRI | CT management |
|---|---|---|---|
| **Bosniak grade 1**<br>Simple cyst imperceptible wall, rounded<br>Percentage malignant: ~0% |  |  | None |
| **Bosniak grade 2**<br>Minimally complex a few thin <1 mm septa or thin calcifications; non-enhancing high-attenuation (due to proteinaceous or haemorrhagic contents) and generally well marginated.<br>Percentage malignant: ~0% |  |  | None |
| **Bosniak 2F**<br>Minimally complex increased number of septa, minimally thickened with nodular or thick calcifications there may be perceived enhancement of hairline-thin smooth septa. Cyst diameter of ≥3 cm.<br>Percentage malignant: ~5%[1] |  |  | Follow-up: needs ultrasound/CT follow up - no strict rules on the time frame but reasonable at 6 months |
| **Bosniak grade 3**<br>Indeterminate thick, nodular multiple septa or wall with measurable enhancement, hyperdense on CT (see 2F)<br>Percentage malignant: ~55%[1] |  |  | Treatment/work-up: partial nephrectomy or radiofrequency ablation in elderly or poor surgical candidates |
| **Bosniak grade 4**<br>Clearly malignant solid mass with a large cystic or a necrotic component<br>Percentage malignant: ~100% |  |  | Treatment: partial or total nephrectomy |

**Table 105.1** Bosniak classification of renal cysts. Comparison between CT and MRI imaging findings.

radiological evaluation is required to plan the surgical strategy and to avoid potential complications. Three-phase renal CT with precontrast, nephrogram, and delayed images is the gold standard among imaging modalities. It gives crucial information about the number, size, location, exophytic/endophytic growth of the renal cyst, and its relation to renal hilum, the pyelocalyceal system, and proximal ureter. Moreover, it allows the relation with contiguous structures such as bowel, liver, or spleen and Bosniak classification to be identified. Finally, this study can guide surgeons on the decision as to what surgical approach to use. In general, a transperitoneal approach is indicated for cysts located in the anterior renal face or parapelvic or when concomitant diseases have to be treated, such as stones affecting the ipsilateral kidney [15]. The retroperitoneal approach is more appropriate for posteriorly located or inferior pole cysts.

In patients where CT is contraindicated (i.e. chronic kidney disease or previous contrast medium reactions), abdominal MRI is a valid alternative. Previous surgical history, body mass index (BMI), and patient comorbidities should be ruled out in order to choose the most suitable therapeutic approach.

Patient preparation includes a complete evaluation of previous abdominal surgical procedures or diseases in order to exclude situations which may impair laparoscopic treatment (i.e. previous transperitoneal procedures, open surgery procedures, hepatosplenomegaly, chronic obstructive pulmonary disease, kyphoscoliosis, or coagulation disorders) [20].

An adequate preoperative bowel preparation regime is required for the transperitoneal approach, but is not useful for the retroperitoneal one. Trichotomy of the surgical access point is necessary and the surgical site should be marked before access to the operating room. A detailed informed consent including surgical procedure and potential complications should be obtained from the patient. Prophylactic antibiotic is given at the time of general anesthesia induction and a Foley urethral catheter is placed before patient positioning. An orogastric tube is only required for transperitoneal procedures.

### Operating room configuration and patient positioning

Once general anesthesia has been administered, patient positioning maneuvers can begin, according to the type of approach being used. The operating room configuration is independent of the type of approach selected. All members of the operating room team can visualize the procedure from a principal monitor placed on the opposite side from the surgeon. The primary tower with insufflator, light source, and camera box has to be visualized by the surgeons in order to be able to modify the setting during the procedure. For transperitoneal approach, the surgeon and assistant are on the contralateral side of the renal cyst, facing the patient's abdomen (Figure 105.1); for retroperitoneal approach, the surgeons stay behind the patient's back (Figure 105.2).

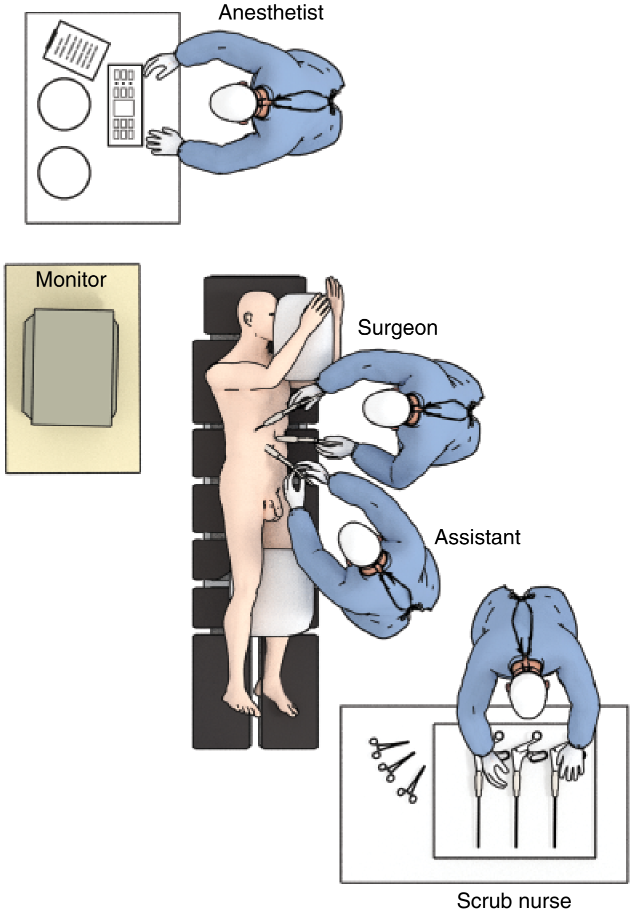

**Figure 105.1** Operating room configuration for transperitoneal right renal cyst decortication.

The table is slightly split in order to have tension on the interested flank. This position is also achieved by using light Trendelenburg placement and by putting a raising towel under the contralateral flank. For the transperitoneal procedure the patient is placed in a modified flank position with a 45° of patient angulations to the operating table. For the retroperitoneal approach, the patient is placed in a full flank position. Moreover, the working space is increased by splitting the operating table at the lumbar level in order to achieve a wide space between the iliac crest and the 12th rib.

All pressure points (including contralateral elbow, legs, and ankles) are properly padded to avoid decubitus lesions. An axillary roll is preferred to protect the contralateral brachial plexus. The lower leg is flexed and the upper one is kept extended and some pillows are positioned between them in order to avoid direct pressure

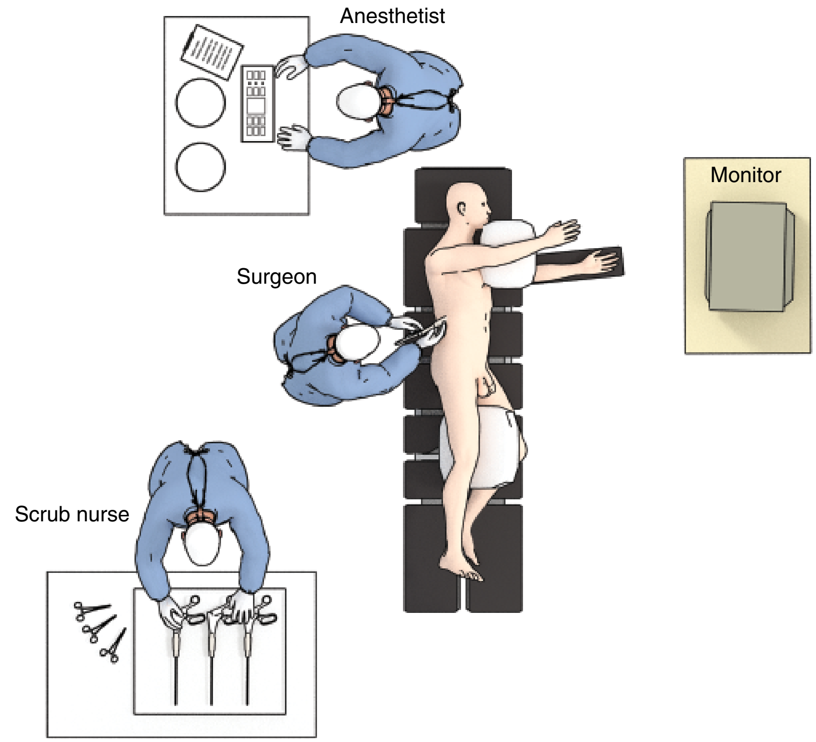

**Figure 105.2** Operating room configuration for retroperitoneal right renal cyst decortication.

contact. The umbilicus is at the level of the operating table break. The patient is secured to the operating table with wide tape at the level of axilla, hips, and legs. The surgical field is prepared and painted with povidone–iodine (Betadine®) from the nipples to pubis level and from the contralateral pararectal space up to the level of the spine.

Laparoscopic access can be achieved using different techniques, depending on surgeon personal experience and patient characteristics [21].

### Trocar positioning – transperitoneal procedure

For laparoscopic transperitoneal access we prefer to adopt a linear port configuration, rather than the triangulation rule as classically depicted. As described by Harper et al., three 5 mm trocars are positioned on the ipsilateral pararectal line [22]. The camera trocar, cranial, with a 30° lens, is positioned two fingerbreadths below the costal margin on the site where the Veress needle was previously placed in order to achieve a 15 mmHg pneumoperitoneum. The other ports are then positioned with a distance of four fingerbreadths between them under direct vision. This trocar positioning avoids interference between surgeon and camera assistant and improves the ergonomics (Figure 105.3) [15]. In the case of obese patients, all ports can be positioned more laterally, according to patient habitus. A low transverse incision such as Pfannenstiel is performed if needed for extraction of surgical specimen.

### Trocar positioning – retroperitoneal procedure

As the retroperitoneal approach gives a smaller working field and a limited area for port positioning, particular maneuvers are needed in order to achieve ideal access. The patient is placed in a fully flank position without any angulation, in order to displace the posterior peritoneum as far as possible. The first 5 mm trocar is placed under direct vision along the posterior axillary line halfway between the iliac crest and the tip of the 12th rib, in the area called Petit's triangle. By mechanical blunt dissection, the retroperitoneal working space is progressively developed at the same time as $CO_2$ insufflation. Some authors suggest the use of a mechanical balloon dilator, progressively insufflated with 800–1000 ml [23].

The peritoneum is then medialized and two additional 5 mm trocars are positioned along the middle and anterior axillary line at the level of the first trocar site under direct vision. A 5 mm port is used for the optic and the others are the working ports for the surgeon, allowing a good balance between vision and ergonomics [24, 25] (Figure 105.4).

As described, three trocars are usually needed for this approach. A useful alternative is the application of laparoendoscopic single-site (LESS) surgery. After the application of the 5 mm single port at the level of Petit triangle, the intervention is performed without the need for further cutaneous incisions. Modern 5 mm flexible tip laparoscopes aid laparoscopic skilled surgeons to

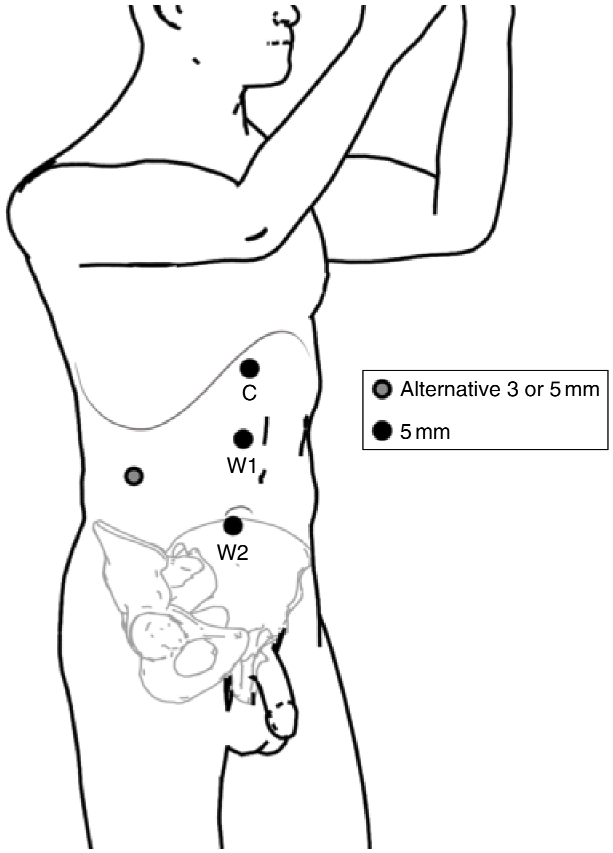

**Figure 105.3** Port placement for transperitoneal right renal cyst decortication. Three 5 mm trocars are positioned on the ipsilateral pararectal line. C, camera port for the assistant; W1, W2, working ports for the surgeon.

make this intervention an effective and feasible alternative to conventional laparoscopy [26] (Figure 105.5).

### Surgical technique – transperitoneal procedure

The first passage consists in kidney exposition. After trocar placement, the parietal peritoneum is excised along the white line of Toldt laterally to the whole extent of descending colon on the left side and of ascending on the right side. On the left, phrenocolic, lienorenal, and splenocolic ligaments should be divided. On the right, liver retraction is useful to fully expose the upper pole of the kidney, and the renal hilum is exposed by means of full medialization of the colon and duodenum. For medially located cysts, a Kocher maneuver is needed to provide full exposition. For a large cyst there is normally no doubt about cyst location as it is fully evident, usually displacing perirenal adipose tissue and adjacent organs. The cyst is then opened with laparoscopic scissors and the cystic liquid aspirated and sent for cytological exam if neoplasia is suspected. The cyst wall is then fully excised with laparoscopic scissors (Figure 105.6), extracted with an Endo Catch® bag and sent for pathological evaluation. Usually some biopsies of renal parenchyma at the base of the cyst are taken. The base of the cyst is then fulgurated with bipolar or monopolar coagulator to achieve perfect control of hemostasis, usually further improved by apposition of local hemostatic agents such as oxide cellulose sponge. If an inadvertent lesion of the collecting system has occurred, immediate repair is performed with continuous suturing. Final inspection is mandatory for hemostasis and absence of urinary leakage. A drain is usually placed from one of the ports. The abdomen is desufflated, peritoneal cavity exited, and port entry sites closed. If a collecting system lesion is noticed, the open-ended ureteral catheter can be substituted with a double-J ureteral stent, which is usually left in place for one month and removed in ambulatory regimen.

In the case of parapelvic or suspected complex cysts, intraoperative ultrasound is needed to define their nature and location. Moreover, for parapelvic cysts, a ureteral catheter should be placed at the beginning of the procedure with two aims: first, to permit the execution of a retrograde pyelography, which will help the surgeons to clarify the relation between the cyst and collecting systems; and second, to allow confirmation of the absence of communication between the cyst and collecting

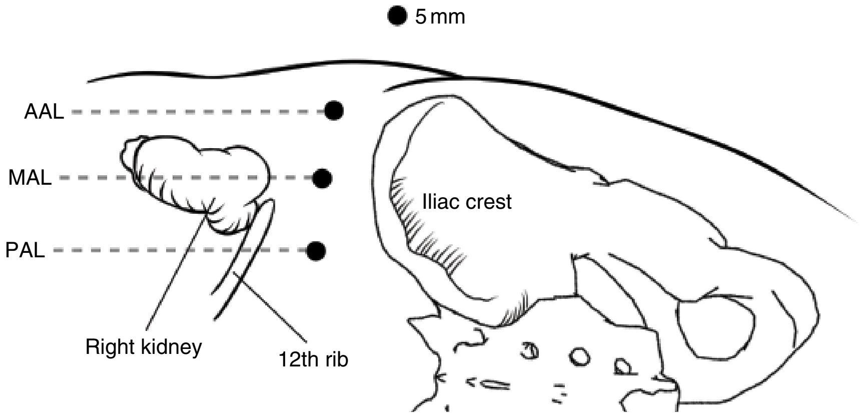

**Figure 105.4** Port placement for retroperitoneal right renal cyst decortication. The first 5 mm trocar is positioned along the posterior axillary line (PAL), halfway between the iliac crest and the tip of the 12th rib. The two other trocars are positioned on the same line as the first, respectively along the medial axillary line (MAL) and the anterior axillary line (AAL).

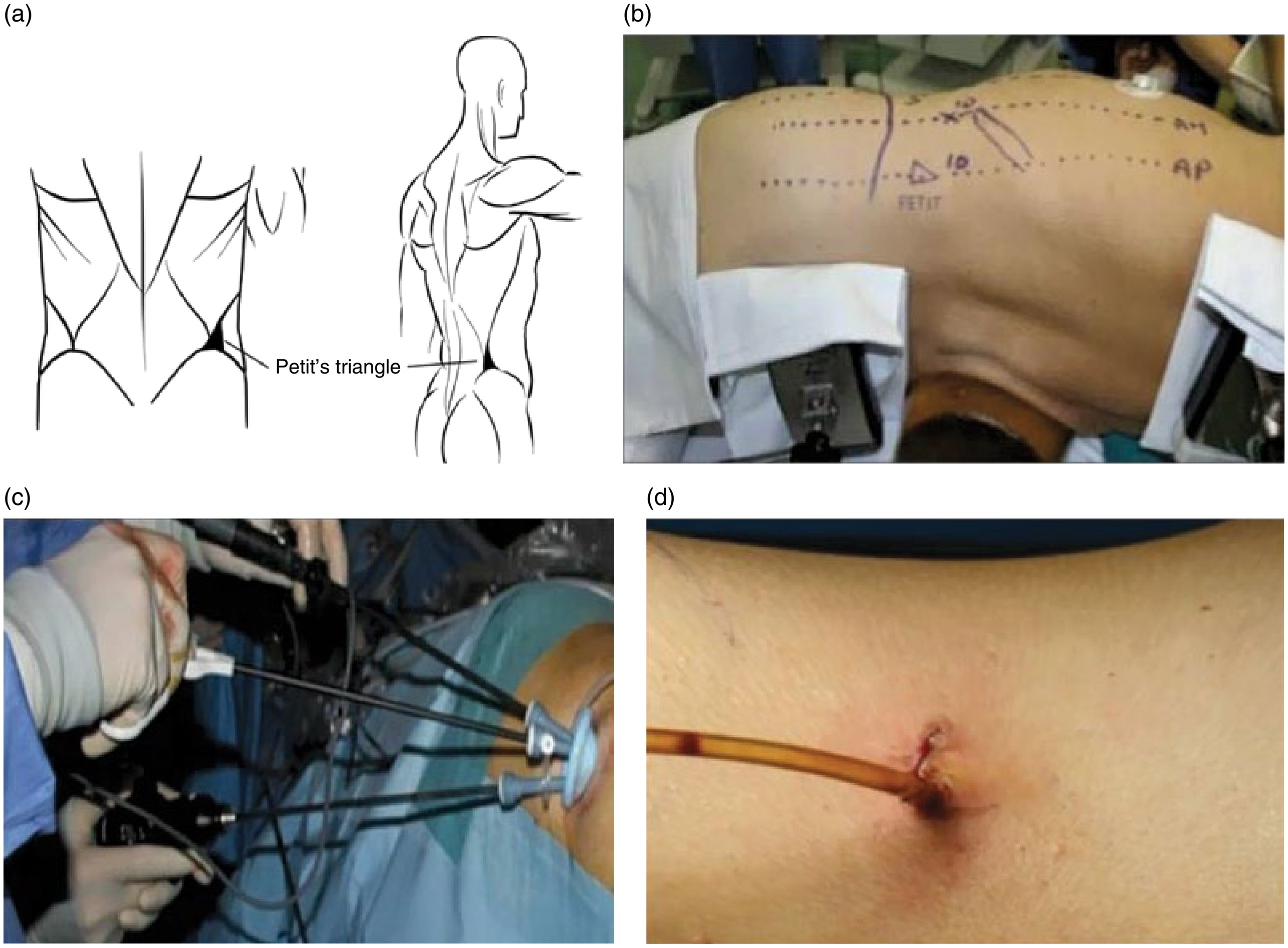

**Figure 105.5** Laparoendoscopic single-site (LESS) surgery summary. (a,b) Anatomical landmarks of Petit's triangle, preferred entry point for retroperitoneoscopic LESS surgery. (c) Instrument positions during the surgical procedure. (d) Final surgical scar.

systems. If an intraoperative lesion is suspected, indigo carmine can be injected via the ureteral catheter: if blue liquid is aspirated from the cyst it must be due to a communication with the urinary system.

### Surgical technique – retroperitoneal procedure

Once retroperitoneal access is obtained, the cyst is usually suddenly recognizable as it dislocates the parietal peritoneum medially and its landmarks are clearly distinguishable from the main muscles of the lateral lumbar region, psoas major, and quadratus lomborum. Medially to psoas muscle, the ureter can be identified and followed up to renal hilum. After identification of the cyst, the surgical technique of removal is the same described for transperitoneal approach.

Retroperitoneoscopy is commonly advised for posteriorly located and lower pole cysts; however, some authors utilize this technique for any kind of renal cysts. Moreover, retroperitoneal access can potentially avoid intraperitoneal tumor seeding in case a malignant cyst is detected [27]. A recent multicentric retrospective study by Ozcan et al. investigated a cohort of 40 patients who underwent laparoscopic transperitoneal or retroperitoneal approach for simple renal cyst decortication. The results of this comparison were slightly in favor of the retroperitoneal approach as it was associated with a relative but significant reduction in operative time and postoperative pain [28].

## Robotic surgery applications

To the best of our knowledge, robot-assisted treatment is not indicated for simple renal cysts. We believe that this kind of surgery is perfectly managed with laparoscopy and that robot-assisted surgery should be reserved for more complex pathologies. Akca et al. recently described a comparison between cystic and solid renal neoplasms treated with a robot-assisted partial nephrectomy. They concluded that surgical outcomes in terms of oncologic radicality and preservation of renal function are equal when treating a suspicious cystic or solid renal neoplasm. Nephron-sparing surgery can therefore be safely proposed for those patients [29, 30].

## Single-site surgery

LESS surgery has been developed in an attempt to further reduce the invasiveness and reduce the cosmetic impact associated with conventional laparoscopic surgery [31]. Many clinical series have demonstrated that LESS surgery is feasible for a broad range of retroperitoneoscopic urologic procedures [26].

The main limitations to the widespread application of this technique are technical problems, such as clashing of instruments and loss of triangulation, which have limited LESS surgery to just a few highly qualified centers. To overcome these problems, robotic technology has been applied to single-site surgery and some patient series have started to appear in the literature, demonstrating the benefits and applicability of this technique [32, 33].

An interesting report by Haber et al. described the clinical application of an innovative device (SPIDER surgical system, TransEnterix, Morrisville, NC, USA) that facilitates LESS procedures, restoring the ergonomics of laparoscopic triangulation and avoiding instruments clashing. The first case reported was decortication of a Bosniak II left renal cyst. The SPIDER system was introduced through a GelPOINT and vision was through a 5 mm flexible-tip laparoscope (EndoEYE, Olympus, Orangeburg, NY, USA) inserted through a static channel of the SPIDER platform [34].

An example of retroperitoneoscopic LESS surgery application is presented in Video 105.1, where we show the decortication of a 10 cm renal cyst. At preoperative CT scan evaluation, three months before surgery, the appearance was of a simple Bosniak I renal cyst. Intraoperatively, we discovered it was hemorrhagic. An intraoperative frozen section confirmed that the lesion was benign and we easily completed cystic wall excision. Postoperative follow-up was negative for recurrences or complications. This case demonstrates how even a simple cyst can become complicated (i.e. for a traumatic event) and may modify its appearance in a short period of time.

## Postoperative management and follow-up

Patients are fully mobilized from the day after surgery. The bladder catheter is removed when drain output is minimal or when drainage creatinine levels are comparable to those in serum, usually few days after surgery. If the output remains absent, the drain is removed the day after bladder catheter removal. Patients are usually dismissed on day 1–3 after surgery, depending on cyst complexity.

An ambulatory sonography is usually performed 2–3 months after surgery and no other follow-up indications are subsequently necessary.

## Complications

Hemorrhagic lesions or urinary leakage are the most frequent reported complications. Even if they delay patient recovery, their resolution is usually conservative. Other reported complications are linked to chemical peritonitis, which mainly occurs after decortication of cysts in patients with polycystic kidney disease. This may lead to fever, prolonged paralytic ileum, or local pain that can be managed with conservative measures (parenteral antibiotics, hydration, parenteral nutrition) and with prolonged hospitalization [16].

## Laparoscopic treatment of calyceal diverticula

### Introduction

Calyceal diverticula are classically depicted as intraparenchymal outpouchings of renal collecting systems, covered by urothelial epithelium, interconnecting with them by a narrow neck, without a proper draining papilla, resulting in reduced passage of urine [35]. A recent review [36] reports that they are found in 0.21–0.6% of intravenous urographies, with similar prevalence in adults and pediatric populations, and are slightly more common in women than in men (63% vs. 37%). They are more common in the upper pole calyces, with a frequency of 48.9%, versus 29.7% and 21.4% in the middle and lower poles respectively.

Pathological conditions are mostly related to development of stones due to urinary stasis, which is reported in 9–50% of cases. This can be the leading cause of chronic or acute flank pain, hematuria, or recurrent urinary tract infections. In some cases, these events can determine impairment to renal function or parenchymal damage [37].

Even only from case report series, upper urinary tract urothelial carcinoma has been reported as an additional possible disease with a high potential of invasion of the renal parenchyma [38, 39]. Because of the rareness of this finding, our knowledge derives mostly from small patient series or case reports and there is lack of studies that compare different treatment modalities.

Calyceal diverticula pathophysiology is still uncertain. Many authors suggest a congenital origin, during the development of the ureteric bud, even if a clear etiology has never been demonstrated [40, 41]. Other authors have suggested potential acquired causes, such as fibrosis of a calyceal infundibulum, obstruction, neuromuscular or traumatic pathogenesis. Obstruction can be secondary to stone formation or to an infective focus (i.e. an abscess); another factor is the possible development of smooth muscle or autonomic deficiency that creates a sphincter achalasia, with progressive collecting system dilatation, finally resulting in a diverticulum [42].

A morphologic classification divides calyceal diverticula into two types: type I diverticula are smaller and drain into minor calyces; type II are larger and drain into major calyces [43]. An alternative classification of calyceal diverticula was proposed in order to help the management of the related stone disease: type I with open mouth and short neck, more suitable for extracorporeal shock-wave lithotripsy (ESWL); type II with closed mouth and short neck, with more indication for ureteroscopy (URS); types III and IV with closed mouth and long or obliterated neck, passable only by percutaneous nephrolithotomy (PCNL) [44].

### Radiologic findings

The sonographic appearance of calyceal diverticula is similar to that of simple renal cysts, except that they frequently contain mobile stones [45]. CT, urography, or pyelography are essential to clarify the communication with collecting systems. CT is normally sufficient to clarify the diagnosis (Figure 105.7).

A recent report concluded that multiphasic contrast-enhanced CT should be performed in cases of calyceal

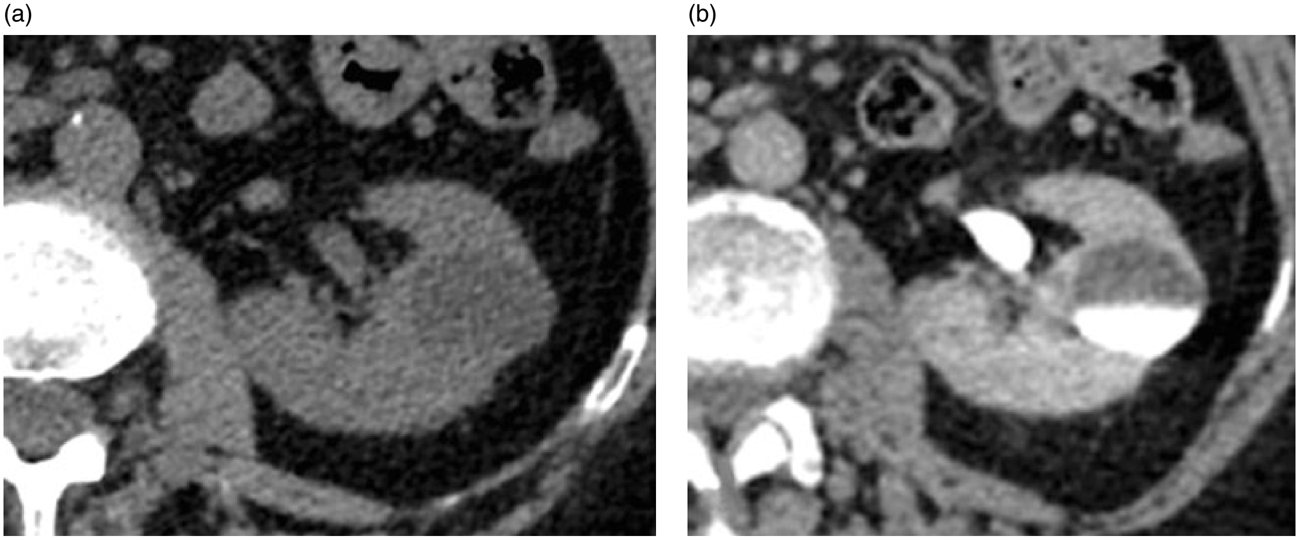

**Figure 105.7** Calyceal diverticulum. CT scan before (a) and after (b) intravenous administration of contrast material in excretory phase. *Source:* Perugia University, Perugia, Italy. Reproduced with permission of Michele Scialpi.

diverticula to rule out the presence of complex atypical Bosniak renal cysts [46].

Other differential diagnoses on imaging can be hydrocalyces, parapelvic cysts, or upper urothelial tumors. Radiologists should be aware of infundibular obstruction to rule out hydrocalycosis, connection with the pelvicalyceal system to exclude cystic disease, or irregular contrast opacification of the cavity for suspicion of neoplasms.

## Indications to surgical treatment

Calyceal diverticula are mostly incidental findings and patients are asymptomatic. Indications to active management are acute or chronic pain, macroscopic hematuria, recurring infections, or parenchymal damage leading to impairment of renal function [47]. Stone-bearing calyceal diverticula are often symptomatic and active management is frequently recommended. As the incidence of this disease is rare, there are no clear therapeutic guidelines. Main options include ESWL or endourological treatments such as URS and PCNL [48, 49].

Because it is the most invasive treatment for this pathology, laparoscopic surgery is indicated in cases of large size stones where previous treatments have failed or for particular anatomic situations such as anteriorly located calyceal diverticula or diverticula with thin overlying parenchyma, where PCNL is not indicated [50]. The goal of laparoscopic intervention is to achieve complete stone clearance and contemporary obliteration of infundibular neck and diverticular cavity.

## Laparoscopic treatment

Both transperitoneal and retroperitoneal approaches have been described; as the incidence of the disease is low, we cannot make a direct comparison between these two techniques. However, the location of the diverticulum, a previous history of major abdominal surgery, and surgeon personal experience should be evaluated before selecting the surgical approach.

First reports were from Gluckman et al. in 1993 [51], who reported a case treated with a five-port transperitoneal access, where the calyx was identified by retrograde methylene blue injection and unroofed, removing the stones and ablating the diverticulum with argon. Hoznek et al. [52] reported in 1998 a series of three patients who underwent renal diverticulum deroofing for intradiverticular lithiasis by a retroperitoneoscopic approach, two with previous failed ESWL and one with an infective complication. After the complete removal of the diverticulum and stones, the authors used a gelatin resorcinol formaldehyde glue on the resection plane. No complications were reported and the early follow-up was negative for recurrences. More recently, Miller et al. [53] reported a series of five patients managed with a retroperitoneoscopic approach in which the diverticulum was identified alternatively by injection of indigo carmine, fluoroscopy, and/or laparoscopic ultrasound. They performed calyceal diverticulectomy, achieving in all cases a complete stone-free rate with fast recovery and without complications. A recent study by Taylor and Thiel [54] compared six cases of minimally invasive calyceal diverticulectomy (four approached laparoscopically and two with a robot-assisted technique). All had history of urinary tract infection and five had associated stone disease. Although the case series is limited, the robotic approach appeared to be feasible and effective, capable of giving results similar to those achieved using traditional laparoscopic surgery. Some authors [55, 56] have also described a combined technique for urolithiasis associated with calyceal diverticula in which, after transperitoneal isolation of the kidney and diverticulum, a transperitoneal PCNL was performed by a nephroscope inserted through an additional 12 mm trocar. This technique minimized bowel lesions and targeted the puncture to the affected diverticulum, improving the stone-free rate and minimizing complications.

Although all these studies have limited series, it is suggested that the laparoscopic approach may have validity for highly selected cases. Despite its invasiveness compared to ESWL and other endourological approaches, perioperative outcomes and long-term follow-up are optimal, without recurrence or late complications reported. Larger studies are still needed in the literature to confirm these statements.

### Operating room configuration, patient and trocar positioning

The operating room is configured in order to give all staff a good view of the procedure, as already observed for renal cyst decortication (Figures 105.1 and 105.2). Monitors are placed on the opposite side from the surgeons. Normally, the first step of the procedure is the retrograde placement of a ureteral catheter in order to perform retrograde pyelography and have an intraoperative marker for the ureter. Thus the patient is initially placed in dorsal lithotomy position. Intraoperative radiological control is needed in order to ensure precise positioning of the ureteral catheter.

After this passage, the patient is positioned for laparoscopic access. As explained for renal cyst ablation, the position varies in order to accomplish the desired surgical approach. The choice of treatment modality is guided by consideration of the patient's habitus and medical conditions and by radiographic evaluation. For an anterior diverticulectomy, the lateral oblique position with

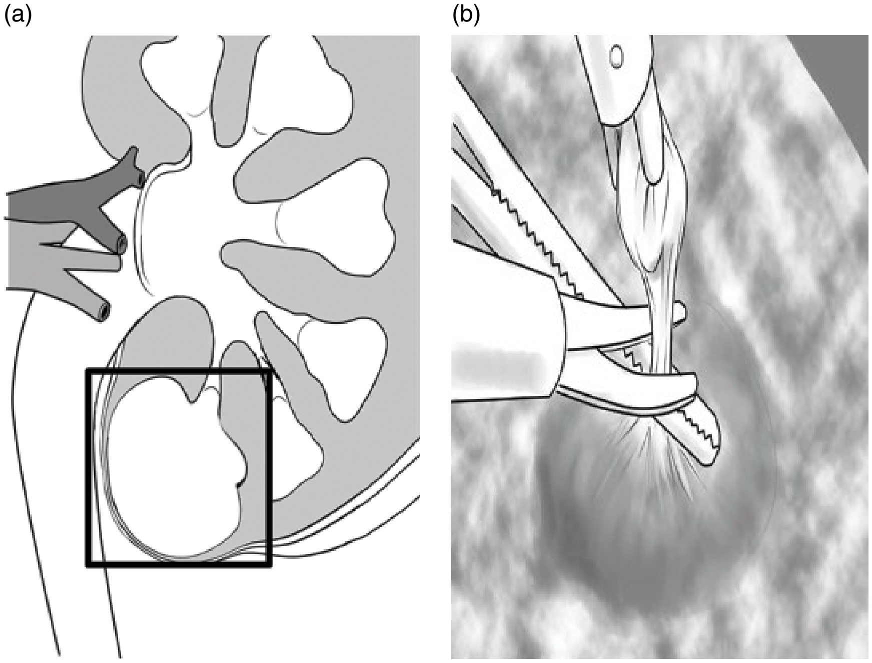

**Figure 105.8** Schematic drawing of a calyceal diverticulum. (a) Coronal morphological view. (b) Diverticular excision after complete isolation of its neck from the sac and the underlying renal calyx.

the torso inclined at 45° is preferred, as for the usual transperitoneal approach to the kidney. If the diverticulum is located posteriorly, a retroperitoneal approach is advisable and the patient is placed in flank position. Consequently, port placement is the same as the one described for laparoscopic renal cyst excision or nephrectomy [57].

**Surgical technique**

The first passage consists of kidney isolation and identification of the diverticulum. Some authors describe the use of intraoperative ultrasound to find the precise position of the diverticulum, and in order to selectively dissect the overlying portion of Gerota's fascia and perirenal fat. It may also help to use insufflation of saline solution via a ureteral catheter in order to distend the wall of the diverticulum. Complete examination of the kidney surface is subsequently performed via laparoscopy. In cases with thick renal parenchyma overlying the diverticulum, intraoperative ultrasound may help the identification of the correct site. A longitudinal nephrotomy is performed with electrocautery scissors on renal parenchyma at the level of diverticulum, in order to gain full exposure of this structure until its infundibulum. Next, the diverticulum is excised as shown in Figure 105.8. Any calculi inside can be grasped with forceps or trapped in an endoscopic retrieval bag or finger glove. Alternatively laser ablation can be used if a combined procedure with a rigid/flexible nephroscope is planned [58]. As the diverticular cavity is excised, deep coagulation is required to ablate the remaining epithelium of the diverticulum and to achieve complete parenchymal hemostasis. The diverticular neck can be dilated for entering the collecting system if a further exploration is demanded (i.e. multiple lithiasis). Otherwise, it is closed with simple interrupted figure-of-eight Monocryl sutures. At this point, further hemostatic materials can be applied locally or injected in order to ensure perfect closure of pyelocalyceal system. A perirenal drain is then positioned through one of the trocars. Ports are then closed and the ureteral catheter is usually left in place for about two days.

**Postoperative management and follow-up**

Patients are fully mobilized from the first day after the procedure. Bladder and ureteral catheters are normally removed on the second postoperative day if the drainage output is minimal. We usually check drainage creatinine levels on the first postoperative day in order to exclude urinary fistulas. If its value is consistent with serum creatinine, leakage can reasonably be excluded.

If there is any suspicion of urinary spilling, the drain and ureteral catheter are left in place until the anastomosis is sealed. Antibiotics are usually administered only at the moment of surgery and suspended if there are no signs of urinary tract infection. A CT is usually performed about one month after the intervention to rule out recurrences, fluid collections, or contrast medium extravasations.

Even with the limited availability of data due to the relatively rare occurrence of this pathology, perioperative outcomes of laparoscopic surgery for calyceal diverticulectomy are encouraging, with optimal long-term results without reports of recurrences.

### Complications

Reports of surgical-related complications in the literature are scarce. Postoperative bleeding requiring blood transfusions, port-site drainage, and subcutaneous crepitance due to pneumoperitoneum are only reported in sporadic cases. All these complications were successfully resolved without the need for invasive treatments. All possible general complications of laparoscopic surgery must be taken into account and explained to the patient before the surgical informed consent is signed.

# Laparoscopic and Robotic Techniques for Management of Pelvic Organ Prolapse

*Sandeep Gurram & Farzeen Firoozi*

*The Arthur Smith Institute for Urology, Zucker School of Medicine at Hofstra/Northwell, Lake Success, NY, USA*

## Introduction

Pelvic organ prolapse (POP) remains a common problem for many women. It is estimated that 50% of women will be affected by POP in their lifetime and the risk for them to receive surgery for POP or stress urinary incontinence (SUI) is 11% [1]. This is particularly relevant given the increasing life expectancy rates, the increased rates of POP in the elderly, and the effect that POP has on quality of life [2]. Some have forecast that the incidence of POP will increase from 3.3 million in 2010 to 4.9 million in 2050, an overall increase of 46% [3]. Definitive therapy for POP is surgical and can be approached primarily through a vaginal or an abdominal approach. In general, vaginal correction is done through a uterosacral ligament suspension or sacrospinous ligament fixation, while abdominal surgery relies on sacrocolpopexy with the use of mesh. A Cochrane meta-analysis demonstrated that the abdominal approach led to decreased rates of recurrent vault prolapse and dyspareunia when compared to the vaginal approach [4]. Even though abdominal sacrocolpopexy has been shown to have greater long-term success, it remains decidedly more invasive, requires longer recovery time, and has a higher complication rate.

The advent of laparoscopy and robotics has led to widespread adoption of these techniques for abdominal sacrocolpopexy (ASC) without evidence demonstrating improved outcomes. Nezhat et al. published the first experience with laparoscopic abdominal sacrocolopopexy in 1994. In this initial technique, the authors advocated using a single piece of Gore-Tex® mesh attached to the posterior vaginal apex with sutures or staples to the sacral promontory [5]. There have been several modifications to this original technique, to reduce operating time, decrease complications, and improve outcomes. For women wanting a uterine-sparing procedure, the laparoscopic sacrohysteropexy has been developed. Some techniques use a single arm of posterior mesh or a combination of Y-shaped anterior mesh with posterior arm of mesh. As volume and experience grew, studies were able to show that although laparoscopic ASC was a longer procedure, it was associated with decreased intraoperative blood loss, shorter hospital stay, and reduced rates of ileus and small bowel obstruction [6]. With the introduction of the da Vinci® Surgical System (Intuitive Surgical Inc., Sunnyvale, CA, USA) surgeons were afforded increased ergonomic capability, more degrees of freedom, and 3D vision. The robotic system gave increased ease of surgery with similar outcomes, albeit at a higher cost [7].

In this chapter, we review the laparoscopic and robotic sacrocolpopexy approaches to the management of POP. We will cover evaluation, technique, complications, and outcomes.

## Evaluation and workup

The primary indication for robotic ASC is the presence of symptomatic apical or uterine POP. The most common symptom is a vaginal bulge or pressure, but this can be accompanied by a considerable number of other urinary, bowel, or sexual complaints [8]. These symptoms can be significantly varied based upon the patient's degree of underlying prolapse. Patients may experience SUI, obstructive urinary symptoms, or even present without any urinary issues but an occult SUI may be unmasked after a prolapse repair. Similarly, contradictory bowel symptoms may also be encountered. Patients may need to excessively strain or use perineal/vaginal pressure to defecate, while others may experience fecal incontinence. The common indications for robotic ASC

include uterine prolapse, post-hysterectomy vaginal vault prolapse, recurrent apical prolapse, and failed previous vaginal repairs. Some factors to keep in mind during the patient selection process include the patient's pulmonary status, ability to tolerate steep Trendelenburg, and any previous abdominal or pelvic surgery which would give rise to concern for postsurgical adhesions.

Patients should undergo a thorough history and physical examination. They should also complete a preoperative voiding diary, in addition to a quality-of-life (QOL) questionnaire. The presence of a uterus should be accounted for and patients should be counseled regarding concomitant hysterectomy or consideration for a sacrohysteropexy. Specific questioning regarding Papanicolaou smear testing history, gynecologic neoplasia, pelvic sonography, and abnormal or postmenopausal uterine bleeding should be pursued.

Physical examination should be thorough, with the use of bimanual examination and both bivalve and univalve speculum examination. This will allow for assessment of all compartments and appropriate staging with the pelvic organ prolapse quantification (POP-Q) system [9]. The estrogen status of the patient should also be noted at this time. The exam should also include a cough stress test to assess for possible SUI though it should be noted that a significant number of patients may have occult SUI that may only be unmasked when the prolapse repair is performed and the urethra is unkinked [8]. Urodynamics may be used in complex cases, but determination of the need for urodynamics should be made on an individual case basis.

In 2006, the Colpopexy and Urinary Reduction (CARE) trial demonstrated that the addition of a Burch colposuspension in women without preoperative SUI who underwent an ASC had significantly lower rates of postoperative SUI (23.8% vs. 44% in the control group) [10]. The long-term outcomes from the CARE trial were published in 2013 and showed that at 7 years, women who underwent concomitant Burch colposuspension at the time of ASC had a longer time to recurrence of SUI compared to those women who did not have an anti-incontinence procedure [11]. Inevitably, there have been those who have used these data to justify prophylactic anti-incontinence procedures to be done concomitantly with prolapse surgery. A more contemporary trial that has echoed this stance has been the Outcomes Following Vaginal Prolapse Repair and Midurethral Sling (OPUS) trial. The OPUS trial concluded that a prophylactic midurethral sling placed during vaginal prolapse surgery resulted in a lower rate of SUI at 12 months postoperatively, albeit at the cost of a higher rate of adverse events [12]. Even though these results seemingly reinforced the CARE trial findings, these were vaginal procedures and cannot be used to directly extrapolate to similar outcomes in ASC, laparoscopic sacrocolpopexy (LSC), or robotic ASC. Our practice is to counsel patients regarding this risk and generally recommend the placement of a midurethral sling concomitantly with the ASC if SUI is experienced clinically or demonstrated during the workup.

## Surgical approach

### Laparoscopic sacrocolpopexy

**Step 1: Preparation**

After induction of general endotracheal anesthesia, the patient is placed in low lithotomy position with the use of Yellowfin stirrups. The patient needs to be secured in order to allow for steep Trendelenburg position and the arms should be tucked in. All pressure points are padded. Both the abdomen and the vagina/perineum should be prepped and a split drape should be employed to allow one assistant to manipulate the vagina while the other assists in the abdomen. A Foley catheter is placed in a sterile manner after draping to allow for further manipulation. A nasogastric tube may also be inserted at this time per surgeon preference.

**Step 2: Abdominal access**

The abdomen is insufflated with either a Veress needle or Hassan trocar in the periumbilical or supraumbilical region. At our institution, we prefer the use of a periumbilical Veress needle, unless there is concern for significant adhesions or chance of bowel injury. If that is the case, Veress needle access can be attempted two fingerbreadths below the costal margin at the level of the midclavicular line. Abdominal pressures should be monitored closely. If the intra-abdominal pressure exceeds 8 mmHg, the needle should be repositioned to ensure it is not in any abdominal structures, adherent to bowel or omentum, or outside the peritoneal cavity. After adequate insufflation, the trocar sites are marked out appropriately (Figure 106.1). Based on surgeon preference, 4 or 5 ports may be used in total. Local anesthesia is administered at each trocar site for preemptive analgesia. A 10–12 mm camera port is then placed at the umbilical edge or slightly cranial to the umbilicus. Two additional 10–12 mm ports are placed lateral to the rectus muscle. One or two additional ports are placed 2–3 cm cephalad and 2–3 mm medial to the anterior superior iliac spines. The sigmoid is retracted to the left and cephalad by using the left lower port.

**Step 3: Posterior peritoneal dissection**

Once the sigmoid colon is retracted, attention is drawn to the sacral promontory. Of note, this left lower port may be obviated by the use of suture retraction.

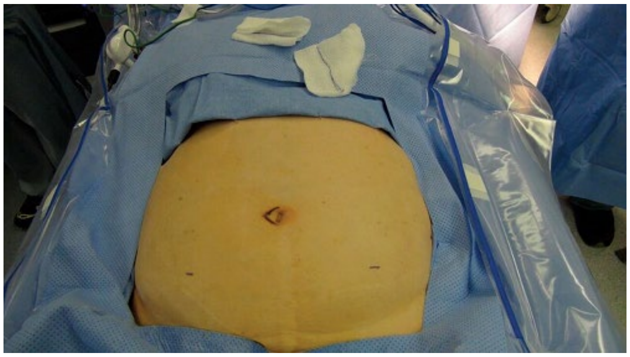

**Figure 106.1** The trocar sites. Typically anywhere from 4 to 5 ports are used, based on surgeon preference. *Source:* Wesley White. Reproduced with permission of Wesley White.

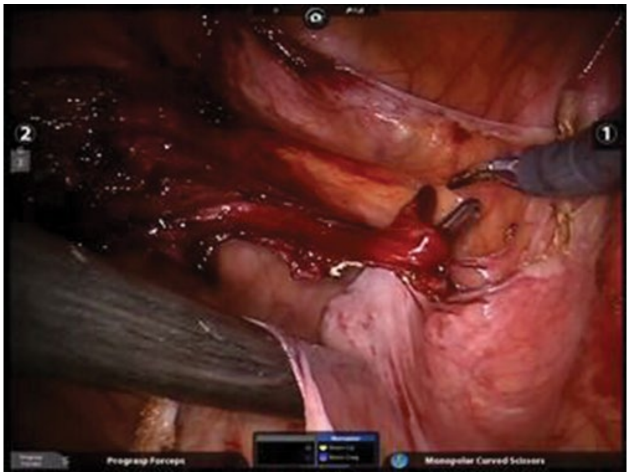

**Figure 106.2** The posterior peritoneum over the sacral promontory has been incised longitudinally to the level of the vaginal apex. *Source:* Wesley White. Reproduced with permission of Wesley White.

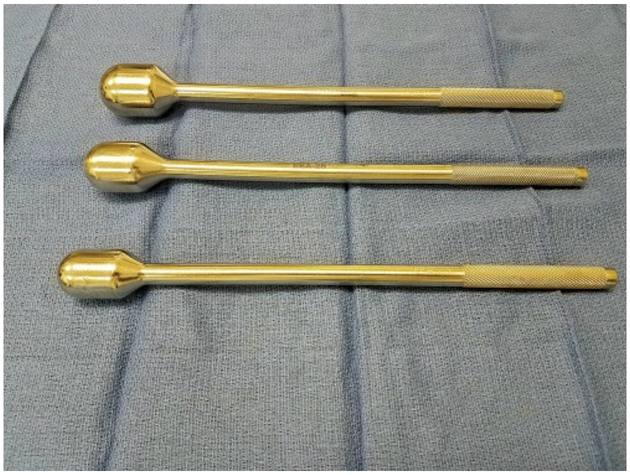

**Figure 106.3** Various sizes of reusable vaginal manipulator are available. The assistant seated at the perineum places the vaginal manipulator, such as the EEA Reusable Sizer (Medtronic, Inc, Minneapolis, MN, USA), inside the vaginal vault. *Source:* Wesley White. Reproduced with permission of Wesley White.

A 1-0 nonabsorbable suture on a large needle (CT-X) can be passed through the left lower quadrant under visualization, placed through an epiploic appendage of the sigmoid colon, and back through the left lower abdomen and clamped to the skin where retraction is desired. Once the retraction of the sigmoid colon is achieved, the sacral promontory, right iliac vessels, and right ureter are identified. The posterior peritoneum over the sacral promontory is incised longitudinally to the level of the vaginal apex (Figure 106.2).

### Step 4: Anterior vaginal dissection

The assistant seated at the perineum will place the vaginal manipulator, such as the EEA Reusable Sizer (Medtronic, Inc, Minneapolis, MN, USA), inside the vaginal vault (Figure 106.3). In general, a larger size such as the 31 or 34 mm is preferred as it distends the vagina more and allows for better vaginal support to aid in dissection. It is imperative that the assistant place the manipulator at the middle of the apex or cervical cuff in order to allow for equal distention of the vagina and prevent redundant tissue being presented. The assistant should place the vagina at a slight downward tilt in order to better expose the anterior vaginal wall to the surgeon. A grasper is used to lift the peritoneum at the vaginal apex following a hysterectomy or the cervical cuff following a supracervical hysterectomy. If the patient is post-hysterectomy, the midline of the vaginal cuff is identified. The peritoneum is incised and the avascular areolar plane between the anterior wall of the vagina and the posterior wall of the bladder is developed. Much of this space can be bluntly dissected with minimal use of cautery for hemostasis. The dissection is carried distally to the level of the bladder neck and laterally to the lateral walls of the vagina. The bladder neck is identified by the location of the Foley balloon. Excessive bleeding or difficulty dissecting the plane can be indicative of entrance into the wrong plane. If the dissection plane is difficult to identify, retrograde filling of the bladder may help further define the anatomy and identify any inadvertent bladder injuries made during the dissection. A cystoscope may also be introduced and its light may be used as a guide. If a bladder injury or vaginal wall injury is made during the dissection, it should be closed in multiple layers with absorbable suture and care must be taken not to place mesh directly on the suture line of the original injury.

### Step 5: Posterior vaginal dissection

The posterior peritoneum is incised at the level of the cervical cuff or vaginal apex. The assistant at this point should shift the vaginal manipulator superiorly in order to allow for better exposure of the posterior vaginal wall. Once again, an avascular areolar plane is encountered and should be approached in a manner similar to that used for the anterior plane. It should be noted that the rectovaginal space tends to be more areolar and may require more sharp dissection than the vesicovaginal plane. The lateral limits of dissection are defined by the uterosacral ligaments and the distal limits are either the peritoneal reflection or preferably down to the level of the peritoneal body.

#### Step 6: Identifying and developing the sacral promontory

In general, the sacral promontory is easily palpated once adequate retraction has been placed on the sigmoid colon and mesentery. The sacral promontory at the level of S1 will be moderately flat and then starts to curve inferiorly at the level of S2. The posterior peritoneum should be incised at the sacral promontory approximately 2 cm proximal to the palpable inferior curve. This peritoneal incision is carried distally and is connected to the posterior wall incision. Take care to stay medial to the ureter and lateral to the sigmoid mesentery throughout this maneuver. If bleeding is encountered in the presacral space, insufflation may be increased in order to tamponade bleeding before placing lap pads to apply direct pressure. Sutures, surgical clips, and hemostatic agents may be used to stave off persistent bleeding.

#### Step 7: Distal placement of mesh

Either a prefashioned Y-shaped polypropylene mesh or two single arms of mesh are trimmed to the anatomic specifications of the patient (typical size variation: 2–4 cm × 12–15 cm). The mesh is rolled and introduced into the abdomen. One arm is unrolled and placed upon the anterior aspect of the vagina and attached via multiple 2-0 Gore-Tex sutures, typically three rows of two sutures. If full-thickness passes are made, they do not need to be removed as they will eventually granulate over. However, full-thickness passes may cause bunching and scalloping of the vagina and are best avoided. The same is repeated on the posterior portion with the second arm of the mesh.

#### Step 8: Fixation of the proximal mesh/coverage of mesh

The tail of the mesh should then be placed over the peritoneal incision. The assistant at this point should be placing pressure with the vaginal manipulator in order to bring the vaginal apex closer to the sacral promontory. The mesh should then be affixed to the anterior longitudinal ligament using two to three 0 nonabsorbable sutures. These should be placed in a transverse fashion as it has the added effect of ligating any vertically oriented vessels at this location. The retroperitoneum is then closed over the mesh (retroperitonealization of mesh) with a running barbed suture.

#### Step 9: Closure

The uterus is removed at this point via the umbilical port, typically hand-morcellated in a plastic bag through the incision in a controlled fashion. Alternatively, the uterus can be removed whole by stressing the umbilical port. The abdomen is desufflated and the ports are removed. Fascia is closed in all 10–12 mm trocar sites with 0-Vicryl figure-of-eight sutures. Skin incisions are closed in a subcuticular fashion.

#### Step 10: Vaginal examination and cystoscopy

A vaginal examination is performed at this time to assess both apical support and to check for occult cystocele or rectocele. After repair of these defects, cystoscopy is performed to assess for any bladder wall injury and for ureteral efflux. The Foley catheter is then replaced and vaginal packing placed.

### Postoperative care

The Foley catheter and vaginal packing are removed in the morning of postoperative day 1. We generally employ a "fill and pull" technique, in which the bladder is filled with 300 ml of saline or as much as the patient can tolerate (whichever is less) and the Foley catheter is removed. The patient is generally discharged home on postoperative day 1 and then reassessed at one month and six months postoperatively.

We describe the robotic laparoscopic sacrocolpopexy approach in the next section as the basic steps are very similar to the laparoscopic approach.

### Robotic laparoscopic sacrocolpopexy

#### Step 1: Preparation

After induction of general endotracheal anesthesia, the patient is placed in low lithotomy position with the use of Yellowfin stirrups. The patient needs to be secured in order to allow for steep Trendelenburg position and the arms should be tucked in. All pressure points are padded. The patients breast should also be carefully padded and taped into position. Both the abdomen and the perineum should be prepped and a split drape should be employed to allow one assistant to manipulate the vagina while the other assists in the abdomen. A Foley catheter is placed in a sterile manner after draping to allow for further manipulation. A nasogastric tube may also be inserted at this time per surgeon preference.

#### Step 2: Abdominal access

The abdomen is insufflated with either a Veress needle or Hassan trocar in the periumbilical or supraumbilical region. At our institution, we prefer the use of a periumbilical Veress needle, unless there is concern for significant adhesions or chance of bowel injury. If that

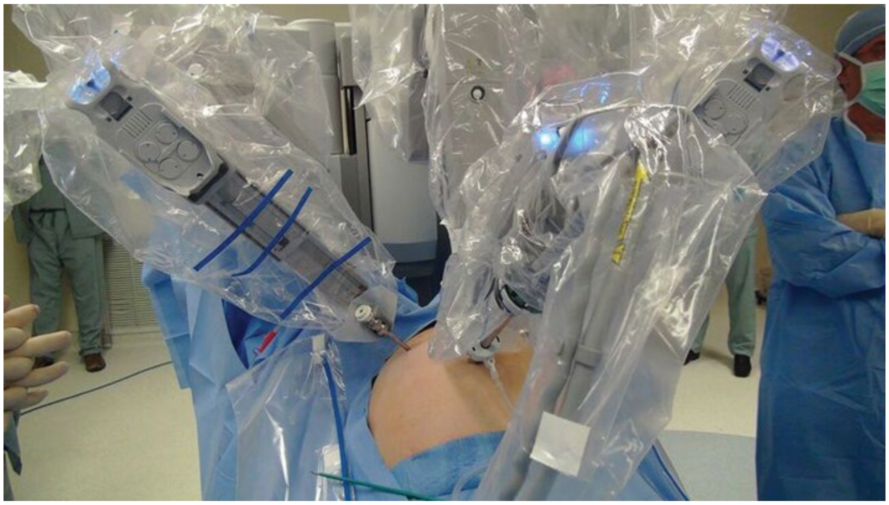

**Figure 106.4** One of the standard distributions of ports for robotic ASC. At our institution, we employ the AirSeal (SurgiQuest, Milford, CT, USA) system for constant pneumoperitoneum and smoke evacuation. *Source:* Wesley White. Reproduced with permission of Wesley White.

is the case, Veress needle access can be attempted two fingerbreadths below the costal margin at the level of the midclavicular line. After adequate insufflation, the trocar sites are marked out appropriately. Local anesthesia is administered at each trocar site for preemptive analgesia. A 12 mm camera port is then placed at the umbilical edge, depending on the robotic system being employed. If the patient has a shorter pubic symphysis to umbilicus length, the trocar can be placed in a supraumbilical fashion with a longitudinal incision. A da Vinci robotic 0° or 30° camera (Intuitive Surgical) is then used to inspect the abdomen. Two 8 mm robotic ports are then placed 9 cm lateral to the umbilicus at the same level. Another robotic port is placed 3 cm lateral and 3 cm cephalad to the left-sided 8 mm robotic arm. At our institution, we employ the AirSeal® (SurgiQuest, Milford, CT, USA) system for constant pneumoperitoneum and smoke evacuation. A 12 mm incision is made 3 cm lateral and 3 cm cephalad to the right 8 mm robotic port,and an AirSeal trocar is inserted (Figure 106.4).

**Step 3: Robotic setup**

The patient is now placed in steep Trendelenburg in order for the bowel to fall away from the pelvis. The patient cart of the robotic system is brought in either at the foot of the bed or docked at the patient's side. We prefer docking the patient cart at the patient's side in order to allow an assistant to be seated by the patient's perineum. We prefer to use right-handed monopolar shears and left-handed ProGrasp forceps. The fourth arm will use an atraumatic grasper such as a double fenestrated grasper. If needed, adhesiolysis is performed in order to have full access to the pelvis.

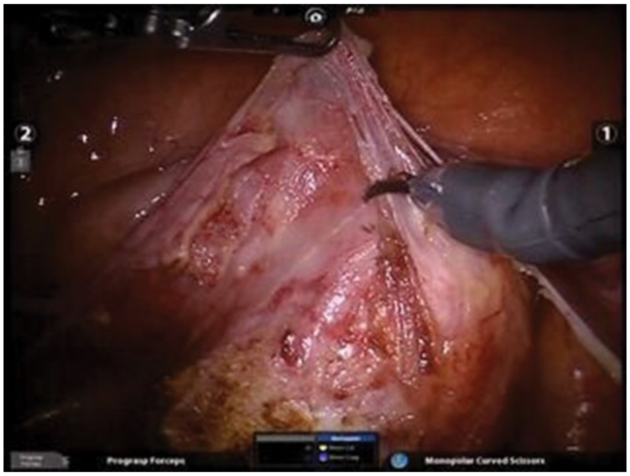

**Figure 106.5** The peritoneum is incised and the avascular areolar plane between the anterior wall of the vagina and the posterior wall of the bladder is developed. Much of this space can be bluntly dissected with minimal use of cautery for hemostasis. *Source:* Wesley White. Reproduced with permission of Wesley White.

**Step 4: Anterior vaginal dissection**

The assistant seated at the perineum places the vaginal manipulator, such as the EEA Reusable Sizer (Medtronic, Inc, Minneapolis, MN, USA), inside the vaginal vault. The ProGrasp is used to lift up the peritoneum at the vaginal apex following a hysterectomy or the cervical cuff following a supracervical hysterecomy. The peritoneum is incised and the avascular areolar plane between the anterior wall of the vagina and the posterior wall of the bladder is developed. Much of this space can be bluntly dissected with minimal use of cautery for hemostasis (Figure 106.5). Once enough of the peritoneum has been dissected, the third arm can be used to hold up the peritoneal edge and maintain countertraction. The dissection is carried distally to the level of the bladder neck and laterally to the lateral walls of the vagina. The bladder neck is identified by the location of the Foley balloon.

### Step 5: Posterior vaginal dissection

The posterior peritoneum is incised at the level of the cervical cuff or vaginal apex. The assistant at this point should shift the vaginal manipulator superiorly in order to allow for better exposure of the posterior vaginal wall. Once again, an avascular areolar plane is encountered and should be approached as described for the anterior plane. It should be noted that the rectovaginal space tends to be more areolar and may require more sharp dissection than the vesicovaginal plane. The lateral limits of dissection are defined by the uterosacral ligaments and the distal limits are either the peritoneal reflection or preferably down to the level of the peritoneal body. Once dissection has started, the surgeon may wish to change his endoscope to the 30° up position for better visualization, though this is not imperative.

### Step 6: Identifying and developing the sacral promontory

The third arm is used to sweep and retract the sigmoid colon to the left and expose the sacral promontory. In general, the sacral promontory is easily palpated once adequate retraction has been placed on the sigmoid colon and mesentery. The sacral promontory at the level of S1 will be moderately flat and then starts to curve inferiorly at the level of S2. The posterior peritoneum should be incised at the sacral promontory approximately 2 cm proximal to the palpable inferior curve. This peritoneal incision is carried distally and is connected to the posterior wall incision. Take care to stay medial to the ureter and lateral to the sigmoid mesentery throughout this maneuver.

Some surgeons prefer to create a retroperitoneal tunnel instead of opening the peritoneal incision completely. The proximal peritoneotomy is made and the ProGrasp forceps are placed inside the incision. Using blunt dissection, the forceps are advanced distally to the level of the posterior vaginal wall dissection. This is meant to allow for quick placement of mesh under the tunnel, but at our institution it has not been noted to significantly alter operative time.

### Step 7: Distal placement of mesh

Either a prefashioned Y-shaped polypropylene mesh or two single arms of mesh are trimmed to the anatomic specifications of the patient. The mesh is rolled and introduced into the abdomen. One arm is unrolled and placed upon the anterior aspect of the vagina and attached via multiple 2-0 Gore-Tex sutures. The sutures are placed in a configuration of three rows with two sutures each. The same is repeated on the posterior portion with the second arm of the mesh (Figure 106.6).

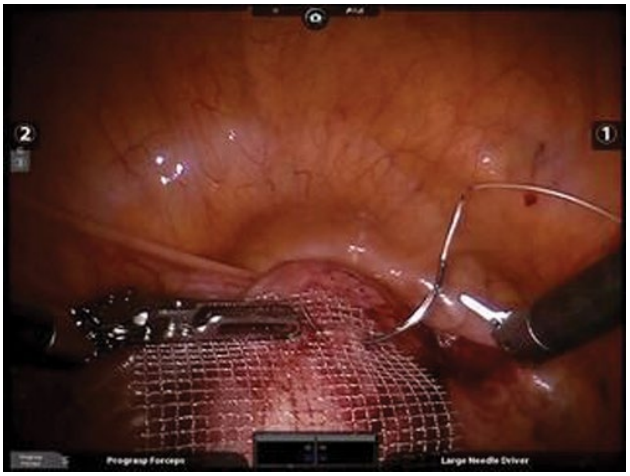

**Figure 106.6** Distal placement of the anterior arm of the mesh. The sutures are placed in three rows with two sutures each. The same is repeated on the posterior portion with the second arm of the mesh. *Source:* Wesley White. Reproduced with permission of Wesley White.

### Step 8: Fixation of the proximal mesh/coverage of mesh

The tail of the mesh should then be placed over the peritoneal incision. The assistant at this point should be placing pressure with the vaginal manipulator in order to bring the vaginal apex closer to the sacral promontory. The mesh should then be affixed to the anterior longitudinal ligament using two to three 0 nonabsorbable sutures. These should be placed in a transverse fashion as it has the added effect of ligating any vertically oriented vessels at this location (Figure 106.7). The retroperitoneum is then closed over the mesh (retroperitonealization of mesh) with a running barbed suture (Figure 106.8).

### Step 9: Closure

The uterus is removed at this point via the umbilical port, typically hand-morcellated in a plastic bag thorugh the incision in a controlled fashion. Alternatively, the uterus can be removed whole by stressing the umbilical port. The abdomen is desufflated and the ports are removed. Fascia is closed in all 10–12 mm trocar sites with 0-Vicryl figure-of-eight sutures. Skin incisions are closed in a subcuticular fashion.

### Step 10: Vaginal examination and cystoscopy

A vaginal examination is performed at this time to assess both apical support and to check for occult cystocele or rectocele. After repair of these defects, cystoscopy is

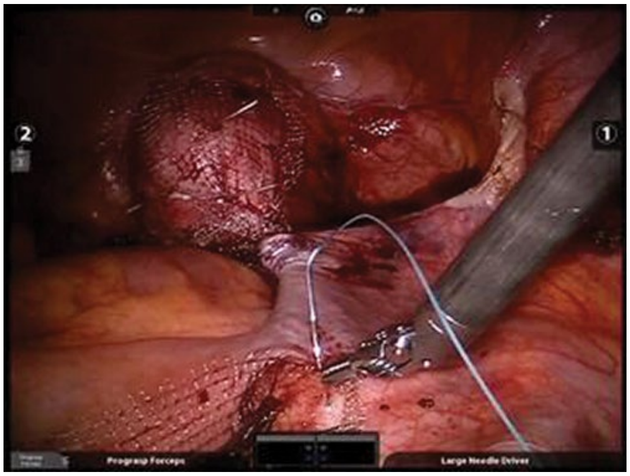

**Figure 106.7** The proximal placement of the mesh entails affixing the arm(s) to the anterior longitudinal ligament using two to three 0 nonabsorbable sutures. These should be placed in a transverse fashion as it has the added effect of ligating any vertically oriented vessels at this location. *Source:* Wesley White. Reproduced with permission of Wesley White.

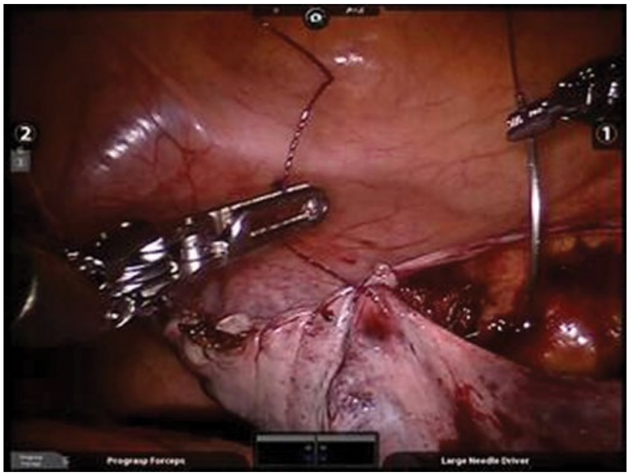

**Figure 106.8** The retroperitoneum is then closed over the mesh (retroperitonealization of mesh) with a running barbed suture. *Source:* Wesley White. Reproduced with permission of Wesley White.

performed to assess for any bladder wall injury and to assess for ureteral efflux. A Foley catheter is then replaced and vaginal packing placed. The postoperative care follows as described in the Laparoscopic sacrocolpopexy section.

### Robotic laparoscopic sacrouteropexy

In patients undergoing sacrohysteropexy, the general steps are similar when comparing laparoscopic and robotic approaches. The preparation and setup are as described earlier. The uterus can be retracted in the laparoscopic approach using a Keith needle or robot-controlled tenaculum. The posterior peritoneum is incised from the sacral promontory to the level of the posterior vaginal cervix. There are two main surgeon preferences for the use of mesh. One includes a single posterior arm, another a combination of a Y-shaped anterior arm of mesh along with a posterior arm. The dimensions of these mesh arms are typically 3–5 cm × 12–15 cm. When a single arm of mesh is used, the mesh is sutured to the posterior vaginal cervix using 0 nonabsorbable sutures. In cases using two arms of mesh, the Y-shaped mesh is passed through the broad ligament on either side, while the posterior arm of mesh is placed as previously described. The proximal arms of the mesh/meshes are then sutured to the sacral promontory as previously described.

## Outcomes

The main goal for the development of LSC and robotic ASC was to replicate the outcomes of ASC but with less morbidity. There have been many studies that have shown this to be the case. In their review, McDermott and Hale reported success rates between 90% and 96% [13]. Granese et al. reported a cure rate of 94.9% in their retrospective study of 165 patients [14], with 5.07% reporting recurrent vaginal vault prolapse and 3.62% reporting a recurrent cystocele. There have also been studies comparing ASC and LSC cohorts with respect to outcomes. Reoperation rates for prolapse were lower in the robotic ASC group compared to the ASC group in one study [15].

Similarly, there have been studies that have shown robotic ASC with cure rates similar to those for LSC. Geller et al. compared robotic ASC and ASC cohorts [16] in a retrospective study comparing 73 patients who underwent robotic ASC with 10 patients who had ASC. The patients had a pelvic exam and objective outcome was measured six weeks postoperatively. The robotic ASC group was found to have higher objective outcomes based on POP-Q score, with C point −9 compared to −8, with all other anatomic outcomes similar between the two groups. The robotic ASC had shorter length of stay (1.3 ± 0.8 days vs. 2.7 ± 1.4 days, $P < 0.001$) and less blood loss (103 ± 96 ml vs. 255 ± 155 ml, $P < 0.001$). The same authors reported on their almost 4-year mean follow-up in the same patient population [17]. Both groups maintained their anatomic success rates. Cure rates for the apex were 100%, with cure rates in the anterior and posterior compartments at 79%. Mesh erosion rates were similar in the robotic ASC and ASC groups (8% and 7%, respectively).

Finally, Paraiso et al. published the first randomized trial comparing robotic ASC to ASC or LSC [15]. At 1-year follow-up there was a difference in anatomical outcomes between the three groups. The study showed that the robotic ASC group had longer anesthesia time and surgical time. In addition, the robotic ASC group had higher rates of pain and required longer use of nonsteroidal anti-inflammatory drugs. From an economic standpoint, the robotic ASC group cost significantly more than the LSC group (mean difference of US$1936, $P = 0.008$).

## Complications

The Pelvic Floor Disorders Network has reported extensively on complications from ASC in the last couple of decades [18]. This comprehensive review reported on intraoperative complications, including cystotomy in 3.1%, ureteral injury in 1.0%, enterotomy or proctotomy in 1.6%, and bleeding or transfusion or both in 4.4%. The most common complication reported postoperatively was urinary tract infection in the median range of 10.9%, followed by wound infection, hematoma, or superficial separation in the median range of 4.6%. Other complications included ileus in 3.6% and deep venous thrombosis or pulmonary embolus in 3.3%. Erosion rate of mesh ranged from 1% to 8%. In terms of reoperation for nonprolapse indications, 1.1% required reoperation for small bowel obstruction and 5% underwent incisional hernia repair. These intraoperative and postoperative complications occurred at relatively the same rate in LSC and robotic ASC when compared to ASC [15].

## Summary

POP is a relatively common problem and may have a significant impact on a woman's quality of life. Several studies have shown that an abdominal sacocolpopexy leads to a more durable response compared to other surgical treatments. LSC and robotic ASC have developed a strong role in the management of POP. Recent data over the last decade has shown both these techniques to have outcomes equivalent to ASC, long considered the gold standard for apical POP repair.

## Introduction

Female genitourinary fistulas are abnormal communications that may occur between the ureter, bladder, or urethra and the uterus, cervix, or vagina. A genitourinary fistula can have devastating effects on the woman. Typically, they present with continual incontinence of varying degree; in some cultures the patient may be ostracized from their family and society, they may suffer depression, loss of employment, and become impoverished. In developed and developing nations alike there is often shame associated with incontinence. Women with fistulas often also develop dermatitis, recurrent urinary tract infections, infertility, and amenorrhea.

The most common cause of female genitourinary fistula in poorer communities is neglected, obstructed labor. Obstructed labor may lead to pressure necrosis of the anterior vagina and posterior bladder, with or without ureteral impingement, from compression between the baby's head and the mother's pubis. Obstructed labor rarely causes ureterovaginal fistula via the same compressive mechanism [1]. In contrast, genitourinary fistulas in developed countries are typically iatrogenic secondary to urologic or gynecologic surgeries for a variety of benign and malignant conditions, or radiation for pelvic malignancies. Iatrogenic fistulas include ureterovaginal, vesicovaginal, urethrovaginal, or vesicouterine fistulas. Rarely, fistulas may occur secondary to a granulomatous infectious process.

Urethrovaginal fistulas are increasing in prevalence due to increasing recognition and surgical treatment of urethral diverticula and the increasing use of midurethral slings [2]. Urethrovaginal fistulas are treated via a transvaginal approach and do not lend themselves to a transabdominal laparoscopic repair. Because of this, they will not be reviewed here.

Most vesicovaginal fistulas are successfully treated via a minimally invasive transvaginal surgery [3]. Vesicovaginal fistulas that have failed prior transvaginal repair, involve a fixed, fibrotic vagina, or are located high in the vaginal vault lend themselves readily to a transabdominal repair. Ureterovaginal fistulas and vesicouterine fistulas are most easily addressed transabdominally and, when appropriate, it is best to use a minimally invasive laparoscopic approach.

Indications are listed in Box 107.1.

## Incidence and prevalence of female genitourinary fistulas

Although the true incidence of vesicovaginal fistulas is unknown, they are estimated to occur in approximately 1/5636 of transvaginal hysterectomies, 1/958 of open hysterectomies, and 1/455 of laparoscopic hysterectomies [4]. Radiation-induced fistula can be divided into early postradiation fistulas caused by tumor necrosis and delayed fistulas secondary to capillary damage with subsequent tissue necrosis and sloughing [5].

## Clinical presentation

Genitourinary fistulas most commonly cause persistent urinary incontinence with an obvious inciting event such as recent obstructed delivery, pelvic surgery, or radiation.

Ureterovaginal fistulas typically present with continual incontinence as urine passes directly from the ureter to the vagina. They may be associated with partial ureteral obstruction, which may give the patient hydronephrosis and flank pain. Vesicouterine fistulas may present with

**Box 107.1 Indications for transabdominal fistula repair.**

**Absolute indications**

- Involvement of the ureteral orifice by the fistula
- Small-capacity bladder requiring augmentation
- Vaginal stenosis from postsurgical scarring or previous radiation
- Involvement of the cervix or uterus
- Coexistent ureterovaginal fistula or ureteral stricture requiring ureteral reimplantation
- Vesicouterine or vesicocervical fistula

**Relative contraindications**

- Previously failed vaginal repair
- Large supratrigonal vesicovaginal fistula

cyclical hematuria, infertility, or amenorrhea (Youssef's syndrome). In the presence of a competent cervix, vesicouterine fistula may also present only with cyclical incontinence of urine during menses [6].

Vesicovaginal fistulas present with incontinence. Urine may pool in the vagina and periodically pass via the vaginal introitus with change in position or increasing abdominal pressure, thus mimicking stress urinary incontinence. Incontinence may be episodic as the fistula may be compressed and obstructed at low bladder volume and pressure and only open with evident incontinence at high pressure or volume. Patients may also develop urinary tract infections, pelvic pain with concomitant urinoma, flank pain if there is hydronephrosis, and perineal dermatitis due to constant moisture on the skin.

## Clinical diagnosis and evaluation

Typical preoperative evaluation at a minimum includes vaginal speculum exam to identify the location of the fistula and the health and viability of the affected portion of adjacent bladder and vaginal tissue. It is important to note during the visual inspection and bimanual exam the relevant vaginal anatomy, including a thorough assessment of vaginal length, signs of inflammation/infection, masses, atrophy, or prior scars. All of these can help aid in surgical planning. If the fistula location is uncertain and not clearly identified on vaginal speculum examination and cystoscopy there are a variety of imaging modalities and bedside tests to employ.

Vesicovaginal fistulas may be identified by instillation of methylene blue dye via a catheter into the bladder, compressing the urethra around the catheter and simultaneously observing for effluent into the vagina.

Ureterovaginal fistulas may also be detected by the double-dye tampon test. This test is performed by administering oral phenazopyridine, placing a tampon into the vagina, and filling the bladder with methylene blue dye. The apical portion of the tampon will reveal orange dye in the presence of a ureterovaginal fistula and blue dye in the presence of a vesicovaginal fistula.

Genitourinary fistulas are also readily identified on contrast-enhanced cross-sectional imaging. Ureterovaginal and ureterouterine fistulas may be identified on images in the pyelographic phase of an intravenously enhanced abdominal and pelvic CT scan or CT urogram. Importantly, the incomplete filling of the bladder as occurs with delayed images of the CT urogram is inadequate to exclude the presence of a vesicovaginal fistula.

A CT cystogram will appropriately distend the bladder and is highly sensitive for vesicovaginal fistula. Cross-sectional imaging may also reveal additional pathology such as urinoma, allow accurate lateralization of ureterovaginal fistula, identify congenital ureteral duplication, presence of hydroureteronephrosis, and thus significantly inform operative planning.

Endoscopic evaluation is also critical. Cystoscopy allows direct visualization of a vesicovaginal fistula, the health of surrounding tissue, and the proximity to the ureters and bladder neck. Cystoscopy may also reveal the presence of foreign material, such as suture, brachytherapy seeds, titanium vascular clips, or calculus. If patient history or clinical suspicions suggest carcinoma, fistula biopsy should be performed at time of cystoscopy. Retrograde pyelography may also reveal the location of ureterovaginal and ureterouterine fistulas.

Some tests for fistula evaluation are summarized in Table 107.1.

## Nonsurgical management

Small, benign, nonirradiated ureterovaginal fistulas may be initially managed by ureteral stent. If retrograde ureteral stent placement is not achieved due to associated stricture, percutaneous nephrostomy with antegrade ureteral stenting may be attempted. If successfully cannulated and stented, an initial trial of ureteral stent may be undertaken for perhaps 6–10 weeks prior to stent removal. If the fistula closes, serial imaging of the upper tract is necessary to observe for delayed stricture formation and need for subsequent endoscopic, laparoscopic, or open repair of the stricture or ureteroneocystotomy. Quality evidence supporting conservative management is poor and limited to case series and expert opinion. Irradiated, large, or malignant ureterovaginal fistulas are unlikely to close

**Table 107.1** Summary of tests for fistula evaluation.

| Fistula type | Test | Diagnostic findings |
|---|---|---|
| Vesicovaginal | Bladder backfill | Bladder is filled retrograde with dilute methylene blue or sterile milk while visualizing the anterior vaginal wall with the posterior speculum blade in place. If no fistula visualized, the catheter is removed and the patient is asked to Valsalva to evalute for stress incontinence |
| Vesicovaginal or urethrovaginal | Double-dye tampon test | Oral phenazopyridine is given and a tampon is placed in the vagina; bladder filled retrograde with methylene blue. Tampon inspected after 10 min: if orange dye is present on tampon, fistula likely urethrovaginal; if blue dye is present likely vesicovaginal. Both colors is combination of both fistulas |
| Urethrovaginal | Trattner double balloon catheter | The upper balloon is inserted through the urethra into the bladder and both balloons are inflated; one balloon is located at the urethrovesical junction and the second at the urethral meatus. Downward traction is placed on the internal balloon which occludes the urethrovaginal junction while the external balloon is pressed snugly against the external urethral meatus; methylene blue or sterile milk is then instilled into the catheter to identify a fistula between the vagina and urethra |
| Vesicovaginal, urethrovaginal, rectovaginal, or colovesical | Direct visualization or imaging | Cystoscopy, CT urogram, or retrograde pyelogram, colonoscopy, proctoscopy, endoanal or transperineal ultrasound, MRI |

with conservative management and are best managed with surgical intervention.

Ureterouterine fistulas may close with hormone therapy to prevent endometrial proliferation and maintain an amenorrheic state [7]. Typically, however, ureterouterine fistulas require transabdominal surgical intervention.

Small, benign, nonirradiated vesicovaginal fistulas may respond to prolonged Foley catheterization that diverts urine and prevents bladder distension. Success with this method ranges from 7% to 15% in case series. Fulguration of a fistula less than 3 mm in diameter is reported as successful in 73–100% of patients in two small series. Fibrin glue injection into the fistula tract has been reported, as has, more recently, fibrin glue combined with platelets and plasma. High cure rates of small fistulas with short-term follow-up are reported [8].

## Goals of surgery

Regardless of etiology, vesicovaginal fistulas can have a devastating impact on quality of life, sexual function, psychological well-being, physical discomfort from incontinence, and increase the risk for recurrent urinary tract infections and therefore damage to the upper tract urothelium. As is the case in most surgery, the first attempt at a surgical repair will be most likely to succeed. Therefore the goal with the surgical repair of vesicovaginal fistulas should be to minimize the number of surgeries, avoid complications and utilize precise surgical techniques to prevent recurrence.

## Timing of surgery for vesicovaginal fistula repairs

Optimal timing of fistula repair is unknown. Formerly, delayed fistula repair was advocated by many [9], but many now advocate for early surgical intervention [10]. Timing of fistula repair is determined by considering several factors, including the benign or malignant nature of the fistula, health and vitality of surrounding tissue, presence of concomitant abdominal or vaginal pathology, and the surgeon's experience and success with varying techniques and approaches. Surgical treatment of large or small, benign, nonirradiated fistula may be pursued without delay. Irradiated, large, or malignant fistula will not close with conservative management, delaying only long enough to optimize tissue health. The surrounding tissue may be optimized by treating any active infection, diverting urine as best as possible with Foley catheter and/or bilateral nephrostomy tubes, waiting for resolution of hematoma or edema, and (in the absence of a contraindication, such as hormonally sensitive cancer or thromboembolic disease) topical estrogen therapy in a low-estrogen state [11].

## Principles of repair

### Approach selection

High vesicovaginal fistula in the proximal vagina or at the vaginal cuff in post-hysterectomy patients may be addressed either transvaginally in experienced hands (not reviewed here) or transabdominally. It is reasonable to proceed to transabdominal repair if inexperienced in complex transvaginal surgery and the variety of interposition flaps raised for transvaginal fistula repair. Transabdominal repair is recommended if a prior transvaginal repair has been attempted previously and failed [12].

Successful extraperitoneal and intraperitoneal repairs have been described [13]. Intraperitoneal repair affords access to omental and peritoneal interposition grafts as well as the ability to perform ileocystoplasty when warranted. An extraperitoneal approach may offer the advantage of avoiding dense intra-abdominal adhesions, though it limits options for interposition grafts to peritoneum, rectus rotational flap, or allograft such as solvent-dehydrated human dura mater.

The best surgical approach is the approach that works best in the individual surgeon's hands. Regardless of the approach, however, the principles of genitourinary fistula repair are the same. Although excision of the fistulous tract is not necessary, debridement of any inflamed, nonviable tissue is critical. Next, wide mobilization of the tissue is required to reduce subsequent tension on the repair. This is followed by apposition of healthy tissue and a watertight closure of the urinary tract with absorbable suture and the closure of the other end of the fistula, be it uterine or vaginal tissue. Finally, it is our preference to deploy an interposition graft of healthy tissue to prevent overlapping suture lines. Urinary diversion with catheters and, when indicated, ureteral stents, is used to divert urine and prevent tension on the repair.

## Optimization for surgery

Early attempts at controlling urinary or bowel leakage can help mitigate skin breakdown and reduce psychological stress. The continuous leakage of urine can cause perineal dermatitis that may make postoperative skin healing more difficult. In the patient with vesicovaginal fistula, the surgeon can consider an indwelling catheter to help prevent perineal dermatitis. Patients often use incontinence products such as pads, diapers, and protective bedsheets to help manage their symptoms. The patient can be counseled on the importance of frequent pad changes to help minimize skin irritation. In addition, topical barrier products such as petroleum, zinc oxide, and dimethicone-based ointments can form an occlusive barrier to prevent skin damage [14].

In some cases, preoperative vaginal estrogen may help with spontaneous closure of the fistula in postmenopausal women with the caveat that there should be no other medical contraindications for the use of estrogen [11].

## Preoperative preparation

Preoperative urine cultures are obtained two weeks prior to surgery and treated according to culture and sensitivities of the infecting organisms. The day prior to surgery, patients are placed on a liquid diet and receive a mechanical bowel preparation with polyethylene glycol or magnesium citrate. Some surgeons advocate use of an enema the morning of surgery, and this is our practice as well. Patients requiring anticoagulation and antiplatelet therapy cease these medications 5–7 days prior to surgery. Prophylactic antibiotics (typically third-generation cephalosporin–cefoxitin at our institution) are given at the time of surgery, ideally an hour prior to incision.

## Operative technique of robot-assisted laparoscopic vesicovaginal fistula repair

Sequential compression devices are placed on the patient's lower extremities, general anesthesia is induced, and endotracheal intubation performed. The patient's arms are tucked alongside the abdomen. All pressure points are sufficiently padded. The abdomen is prepped with chlorhexidine and the genitalia are prepped with betadine scrub, or as dictated in accordance with patient skin sensitivities and allergies. The patient is draped as a single surgical field as the genitourinary fistula traverses both the surgically sterile field of the abdomen and the clean-contaminated field of the external genitalia and fistulized urinary tract. Cystourethroscopy is then performed if open-ended ureteral catheters are to be placed for ureteral access or if ureteral stents are planned. Ureteral catheters or stents are not typically required in the setting of an isolated vesicovaginal fistula high on the posterior bladder wall above the trigone in the midline. Vesicovaginal fistula near the ureteral orifices, trigone, or bladder neck are best addressed after at least placing open-ended ureteral catheters to facilitate later ureteral stent placement if warranted. A Foley catheter is then placed via the urethra into the bladder, balloon inflated, the bladder drained of any residual urine and the catheter clamped.

One may place a separate Foley catheter via the vesicovaginal fistula tract if possible, clamp it, and leave it indwelling to aid in further identification and manipulation of the fistula [3]. Many fistulas are too small to be cannulated this way and those that can accommodate a Foley catheter are typically quite apparent and, in our experience, a catheter is not needed for identification or manipulation. Catheters are clamped to maintain pneumoperitoneum upon later opening of the bladder and exposure of the fistula tract. In addition, the vagina is packed with a wet towel or gauze roll to maintain peritoneum.

The patient is placed in a steep Trendelenburg position. Pneumoperitoneum is achieved by Veress needle insufflation. In patients with few prior abdominal surgeries, the needle is typically placed at the umbilicus. In patients with multiple prior abdominal surgeries, including previous access at the umbilicus, the Veress needle may be placed anywhere below the costal margin as informed by preoperative axial imaging to avoid unexpected hepatomegaly or splenomegaly.

After achieving pneumoperitoneum, the robotic 12 mm optical trocar is placed just superior to the umbilicus and inspection of abdominal viscera performed upon entry. Any necessary adhesiolysis is performed and additional robotic and assistant's ports are placed under direct vision. Several port configurations are described. We use five transperitoneal ports. Two 8 mm robotic ports are placed 9–10 cm on either side of the optical trocar. An additional 8 mm robotic port is placed 4 cm superior to the left iliac crest, 9 cm from the adjacent robotic port, for the fourth robotic arm. An assistant's port, for which we use the 12 mm AirSeal® device (SurgiQuest, Milford, CT, USA), is placed on the patient's right side, 9 cm lateral to the adjacent port and 4 cm above the iliac crest.

The robotic surgical platform, currently da Vinci Si at our institution (Intuitive Surgical Inc., Sunnyvale, CA, USA), is then side-docked to allow ease of access by the bedside assistant to the urethral catheter, any ureteral catheters, vaginal packing, and, if needed, vaginal manipulation probe during the case.

Our starting instruments include two robotic Maryland bipolar forceps (one in the surgeon's nondominant control arm and the other in the fourth arm) and a robotic monopolar curved scissor under control of the surgeon's dominant hand. The assistant can then freely pass sutures and perform retraction via the AirSeal port on the patient's right side.

### Step 1: Delineate the anatomy

Genitourinary fistula patients often require extensive adhesiolysis because of their prior surgeries and the presence of any urinomas or phlegmon. Often, bowel is adherent not just to the peritoneum throughout the pelvis but also to the vaginal cuff or cervix in cases of prior hysterectomy or supracervical hysterectomy, respectively. Fastidious attention is given to mobilizing bowel from the pelvis while preserving posterior peritoneum and omentum, as each may later serve the critical role of interposition grafts to support the fistula repair. The omentum may require mobilization from the greater curvature of the stomach in order to reach the pelvis in as many as 70% of patients. Viability of the omental flap is dependent on preserving the right gastroepiploic artery and thus mobilization is begun high on the left side of the greater curvature. The distal end of the flap is then positioned in the pelvis for later use.

### Step 2: Accessing the fistula

Robot-assisted laparoscopic vesicovaginal fistula repair is a minimally invasive, transperitoneal technique to perform the classic transabdominal repair originally described by O'Conor and Sokol [15].

The peritoneum overlying the bladder is dissected laterally from a midline peritoneotomy. The transperitoneal cystotomy is performed in the midline of the bladder in the dome well above the vaginal wall and fistula site. Cystotomy may be made on a decompressed, empty bladder, but the bladder may also be distended with saline via the urethral catheter (or catheter via fistulous tract if placed previously) for ease of identification. The bladder is opened in the sagittal plain from the bladder dome to the level of the fistula using electrocautery. The current trend is away from a large bivalving of the bladder in favor of a limited cystotomy just above the fistula tract [16].

Polyglactin absorbable stay sutures may be placed through full thickness of the detrusor to facilitate visualization and fistula dissection. These sutures may be temporarily affixed to the superior and lateral abdominal wall using Weck™ hemoligation clips (Teleflex, Morrisville, NC, USA) or similar. Additional retraction may be performed with the fourth robotic arm and by the bedside assistant.

The cystotomy is extended to the level of the vesicovaginal fistula. The fistula itself may be incorporated into the cystotomy, or, if the tract is well epithelialized or necrotic, the fistula may be debrided or excised. We do not recommend wide excision of a benign, nonirradiated fistula tract as it has not been shown to be advantageous and increases the defect that must be repaired. Excision should be restricted to a minimum and only what is required to reach healthy, viable tissue circumferentially. Hemostasis is achieved using bipolar forceps diathermy to minimize thermal injury to surrounding tissue.

### Step 3: Separation of the bladder and vagina

Dissection of the posterior bladder wall from the underlying anterior vaginal wall or uterine segment is performed with blunt and sharp dissection. Posterior reflection of the vagina away from the bladder by the bedside assistant using a Haney retractor or vaginal probe may facilitate dissection. The bladder is reflected anteriorly and again visualization may be aided by additional polyglactin absorbable stay sutures affixed to the anterior abdominal wall. Wide circumferential dissection with a 3 cm radius from the fistula is ideal to facilitate tension-free closure and to anchor an interposition graft.

### Step 4: Closing colpotomy, interposing graft, closing cystotomy in vesicovaginal fistula

Our practice is to close the colpotomy with running, locking polyglactin or poliglecaptone suture, typically 3-0 on a small, tapered needle. A barbed unidirectional suture (V-Loc, Covidien, Minneapolis, MN, USA) is preferred by some surgeons [16].

An interposition graft is then advanced and secured with polyglactin sutures circumferentially around the colpotomy to the vaginal wall in order to completely cover the suture line. Omentum, as previously mentioned, is most often used. In the absence of adequate omentum, a peritoneal flap may be raised from the lateral pelvic wall and secured with polyglactin suture to the vagina. If peritoneum is also inadequately mobilized or of poor quality, a free bladder mucosal graft may be harvested from the luminal surface of the bladder dome, leaving underlying detrusor muscle *in situ*, and securing the graft in place with absorbable polyglactin suture, its mucosal surface toward the vagina [17]. The Gil-Vernet technique involves using a rotational bladder wall flap to slide into the apex of the cystotomy so that the suture lines of the colpotomy and cystotomy do not overlap, similar conceptually to a Y-V plasty that replaces bladder with bladder. This may obviate the need for a separate interposition graft [18].

If there is any suspicion of ureteral injury, ureteral patency is assessed and integrity suggested with intravenous administration of methylene blue or fluorescein dye while observing for dyed effluence of urine from the ureter and ureteral orifice.

The cystotomy is then closed in two layers of polyglactin suture. The first layer incorporates 2–3 mm of urothelium and approximately 7 mm of full-thickness detrusor with each passage of the 3-0 polyglactin suture on a tapered needle. This suturing is performed with a barbed unidirectional suture or in a running, locking fashion the full length of the cystotomy. The bladder is then distended by the assistant with methylene blue-dyed saline and examined for watertight integrity. The bladder is then partially drained and the second layer of closure is performed with 2-0 polyglactin or barbed unidirectional suture in a simple running manner to imbricate the first layer.

### Step 5: Ureterovaginal fistula repair

The technique for ureterovaginal fistula repair differs significantly from repair of a vesicovaginal fistula. The ureter distal to the fistula does not require excision, nor do the bladder and vagina require separation. The bowel is reflected superiorly from the underlying iliac vessels ipsilateral to the ureteral fistula. Dissection may be aided by the presence of a ureteral catheter or stent previously placed, but if the ureter cannot be catheterized, the ureter is identifiable as it crosses the iliac vessels. The peritoneum is incised and the ureter mobilized, taking care to preserve the lateral blood supply of the distal ureter and the medial blood supply of the proximal ureter. Iatrogenic ureterovaginal fistulas nearly always occur in the distal ureter and are amenable to direct ureteroneocystotomy without bladder mobilization and reconfiguration. If the fistula or injury has devitalized more than the distal 4 or 5 cm of the ureter, a psoas hitch or Boari flap are recommended to accomplish a tension-free anastomosis and reduce risk of ureteral distraction.

Direct ureteroneocystotomy may be performed by sharply transecting the ureter as distal as it is viable. An easily reached site on the bladder that ensures a tension-free anastomosis is selected for neocystotomy. The bladder is filled and a short cystotomy performed with the monopolar curved scissor. The medial wall of the distal ureter is incised, widely spatulating the ureter. The lateral half of the ureteral anastomosis is performed with a 4-0 poliglecaprone suture. A 5 Fr multilength double-J ureteral stent is then delivered via the assistant's robotic port and deployed first proximally within the ureter then distally within the bladder. The remainder of the ureteral anastomosis is completed with poliglecaptone suture.

If a tension-free direct ureteroneocystotomy is not possible because of the length of devitalized ureter or more proximal ureteral fistula, we prefer the use of a Boari flap. The apex of the flap is located on the anterior bladder surface with the base of the flap extending posterolaterally toward the affected ureter. The flap is then deflected superiorly and can be held outstretched and in place by the fenestrated grasper of the fourth robotic arm. The robot should be docked ipsilateral to the ureteral fistula for this purpose. The urothelium of the flap is incised in its midline from the apex for a length of 2 cm and the urothelium raised. The ureter then lies in the urothelial defect and is secured with poliglecaptone suture circumferentially. The urothelium of the flap is then closed over the distal 2 cm of ureter with interrupted poliglecaptone suture. A ureteral stent, typically 5 Fr multilength double-J, is deployed and the cystotomy closed in two layers as described above.

### Step 6: Exiting the abdomen

The abdomen is irrigated with saline and examined for hemostasis as pneumoperitoneum is reduced. Once hemostasis is assured, the robot system is undocked. We place a small, closed suction drainage tube via the lateral

8 mm port used for the fourth robotic arm and remove all ports under laparoscopic visualization. We close the 12 mm camera port and the 12 mm AirSeal assistant's port with 1-0 polydioxanone delayed absorbable suture. All port sites are infiltrated with 0.25% bupivacaine and then closed with subcuticular 4-0 poliglecaptone sutures on a cutting needle. Finally, the vagina is packed with a clindamycin cream-saturated gauze that is removed on morning of postoperative day 1.

### Postoperative care

We encourage early ambulation following surgery. Prophylactic antibiotics are continued for 24 hours after surgery while intravenous hydration is limited and diet advanced as tolerated. Most patients experience adequate postoperative analgesia with intravenous ketorolac (renal function permitting) and intravenous narcotics only for breakthrough pain.

Abdominal drain fluid is routinely sent for creatinine the next morning. If compatible with serum creatinine levels and not concerning for urinary extravasation, the drain is removed on the morning of postoperative day 1. Most patients are discharged on postoperative day 1 with the drain removed.

The detrusor is aggressively relaxed to minimize bladder tension and treat symptomatic bladder spasms with scheduled anticholinergic or beta-agonist medications for the duration of the catheterization, which is typically 10–14 days. A voiding cystourethrogram is obtained to ensure bladder integrity prior to catheter removal. If ureteroneocystotomy was performed, the ureteral stent remains indwelling for four weeks. We encourage pelvic rest with nothing placed per vagina for six weeks.

### Results

Since Nezhat and colleagues [19] first reported laparoscopic repair of a vesicovaginal fistula, several series have confirmed the success and reproducibility of the minimally invasive approach [20, 21].

Xiong et al. [22] recently reported their experience with open versus laparoscopic repair in 36 and 22 patients, respectively. The nonrandomized cohorts had similar preoperative characteristics. Patients receiving laparoscopic repair had less blood loss, shorter hospitalization, and equivalent success rates.

Miklos and Moore [23] analyzed their 15-year experience with laparoscopic extravesical technique in 33 patients and report a 97% cure in primary fistula, 100% cure (11 of 11) in recurrent fistulas at mean of 17 months follow-up. They used a three-layer closure without the interposition of a graft in 98% (43 of 44) and observed a 98% (42 of 43) success rate. They similarly had low mean estimated blood loss (39 ml) and short hospitalization (1.1 days mean).

Robot-assisted laparoscopic repair of a vesicovaginal fistula was initially reported by Melamud et al. [24]. Gupta et al. [25] reported on their series of 12 patients with recurrent, nonirradiated vesicovaginal fistula having robotic repair between 2006 and 2008. They found 100% cure rate, mean blood loss of 88 ml, and no complications at mean follow-up of six months [25]. The next largest published single-institution series to date is that reported by Agrawal et al. in 2015 [26]. This included 10 patients with nonirradiated fistulas, 3 with concomitant ureteral reimplantation. Mean operative time in this series was 214 minutes, median length of hospital stay was 1 day, and estimated blood loss ranged from 5 to 100 ml. There were no intraoperative complications. One patient had Clavien–Dindo grade I complication ileus and two had grade II complications of fever with atelectasis and *Clostridium difficile* infection, respectively. At median follow-up of 24 months, all patients were subjectively and cystographically cured [26].

## Ureterovaginal fistula repair

A multinational series of 12 patients undergoing robot-assisted laparoscopic ureteral reimplantation with psoas hitch included two patients with ureterovaginal fistula [27]. The authors reported a similarly low estimated blood loss of 48 ml, 208 minutes of operative time, no complications, and 100% success at 15 months.

## Conclusions

Genitourinary fistula repair is optimized with prompt diagnosis, the appropriate selection of least-invasive surgical approach, and use of interposition grafts as needed, according to the individual surgeon's experience. The vast majority of vesicovaginal fistulas are cured with transvaginal surgery, with or without interposition martius, gracilis, or other flaps. Vesicovaginal fistulas are also highly amenable to a minimally invasive transabdominal approach. Ureterovaginal, vesicouterine, ureterofallopian, and ureterouterine fistulas are nearly always treated with transabdominal approach and each has been successfully repaired in a minimally invasive fashion. Strict adherence to the principles of juxtaposing healthy tissue, a watertight suture line, interposition of viable tissue flap, avoiding overlapping suture lines, prolonged catheter drainage, and minimizing tension on the repair has delivered dramatic improvements in fistula cure rates since surgical repair was first attempted in 1663.

# Laparoscopic, Laparoendoscopic Single-site, and Robot-assisted Living Donor Nephrectomy

*Ganesh Sivarajan & Ravi Munver*

*Department of Urology, Hackensack University Medical Center, Hackensack, NJ, USA*

## Introduction

The first conventional laparoscopic living donor nephrectomy was reported in 1995 and was performed at the Johns Hopkins University. The authors reported that the kidney was removed via a 9 cm infra-umbilical incision, warm ischemia time was limited to under 5 minutes, and the patient was discharged on the first postoperative day [1]. Within 5 years of the initial report, laparoscopic donor nephrectomy was adopted by more than 100 transplant centers over five continents and had been demonstrated to result in shorter hospitalization, less pain, shorter convalescence, and earlier return to work and normal activities for patients postoperatively as compared to standard open donor nephrectomy [2, 3]. Since then, the technique for laparoscopic donor nephrectomy has evolved and spread such that it is considered the standard of care at most institutions for living renal donation. In this chapter, we review and discuss a modern approach to laparoscopic donor nephrectomy with special emphasis on the preoperative evaluation, intraoperative technique, and postoperative care.

## Preoperative evaluation

All potential renal donors should undergo a complete preoperative evaluation to ensure their suitability for renal donation. A thorough medical evaluation, generally coordinated by a transplant nephrologist, to assess for the presence or history of underlying renal disease, microhematuria or proteinuria, nephrolithiasis, transmissible infection (e.g. HIV, hepatitis B or C), hypertension, or other major comorbidities (e.g. diabetes, chronic obstructive pulmonary disease, heart disease, or immunologic disorders). Any abnormalities identified such as microhematuria or elevated blood pressure should be fully worked up prior to undergoing surgery. The comprehensive nature of this workup is critical as every care should be taken to avoid kidney donation in patients with a significantly increased likelihood of developing chronic kidney disease, endstage renal disease, or dialysis dependency following organ donation. In carefully selected renal donors, overall survival and incidence of endstage renal disease appear to be unchanged as compared to the general population [4]. The potential risk of developing chronic kidney disease and endstage renal disease should still be discussed with all patients preoperatively, however, as some studies have suggested that kidney donation may carry an increased lifetime risk of endstage renal disease as compared to healthy, similarly screened, matched control patients [5] or as projected by endstage renal disease models in the absence of donation [6].

A surgical history should be obtained preoperatively, and an abdominal exam should be performed by the operative surgeon to assess for abnormalities or any history of major abdominal surgery which may alter the surgical plan. Although a reported history of intra-abdominal surgery is not a contraindication for laparoscopic donor nephrectomy, it may change the surgeon's decision of extraction site planning or whether to utilize a hand-assisted laparoscopic technique.

It is imperative to obtain a thorough understanding of the renal anatomy prior to undertaking laparoscopic donor nephrectomy. An abdominal and pelvic computed tomography (CT) scan with both angiographic and excretory phases should be obtained. Axial, coronal, and, in many instances, sagittal reconstructions should be meticulously examined to determine the actual position of the renal arteries (and their origins) as well as the position of the initial segmental branches of each artery.

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

The venous vasculature should be assessed for the position of the gonadal and adrenal veins as well as any lumbar veins in the region of the renal hilum. Magnetic resonance angiography is an alternative to CT for evaluation of potential kidneys. Renal scintigraphy is usually obtained when there is a discrepancy in renal size, contrast uptake or excretion, or renal scarring to ensure adequate renal function.

Although accessory renal veins can generally be sacrificed without consequence intraoperatively, they are generally spared quite easily provided they are appropriately identified on preoperative imaging. Finally, both kidneys, the remainder of the abdomen and retroperitoneum, and the great vasculature should be examined for abnormalities such as excessive perirenal adipose tissue, retrocaval ureters, retro-aortic renal veins, renal tumors or masses, nephrolithiasis, and complex renal cysts, which might complicate or contraindicate renal donation. Although the left kidney is traditionally preferred for donation due to the presence of a longer renal vein, the right kidney may be selected in the event of aberrant anatomy or other such patient-specific concerns. Multiple left renal arteries or anomalous left renal vasculature are not absolute contraindications to procuring the left kidney.

All potential donors should undergo routine psychiatric evaluation to rule out the presence of any psychiatric comorbidity that might impair their ability to provide informed consent for renal donation or the presence of any undue coercion from a third party affecting their decision to donate. It is often helpful to provide the renal donor with a "medical representative" unrelated to the transplant team to absolutely ensure that they have an advocate who is completely unbiased. Furthermore, all donors should be reassured that should they change their mind regarding their willingness to donate at any point, the recipient will be informed only that the transplant could not proceed due to "medical reasons." This is imperative in order to ensure that there is no element of coercion, either real or imagined, that clouds a potential donor's decision-making preoperatively.

A multidisciplinary transplant board should be convened to discuss any cases which might be complicated due to recipient medical or surgical history, aberrant renal anatomy, or ethical concerns.

## Surgical risks

Although the rate of major complications (≥Clavien II) following laparoscopic donor nephrectomy has been estimated to be only 1.8% [7], all potential donors should be presented with a comprehensive preoperative discussion regarding expected hospital stay, postoperative pain management, likelihood of blood transfusion, and all potential surgical risks including bleeding, injury to adjacent intra-abdominal structures (e.g. pancreas, spleen, colon, diaphragm, liver, stomach, and small bowel), standard wound-healing complications (e.g. infection, hernia), and the potential need for conversion to an open procedure. The potential for major and potentially catastrophic complications such as deep venous thrombosis, pulmonary embolism, myocardial infarction, stroke, or death should be discussed as well. If the potential donor has a change of heart following this discussion, they should be reassured that the reasons for the transplant cancellation will remain private and undisclosed from the intended recipient.

## Surgical technique

### Left laparoscopic donor nephrectomy

#### Patient positioning

After induction of general anesthesia and placement of an orogastric tube and Foley catheter, the patient should be positioned in a modified flank position with all pressure points adequately padded. We advocate using minimal, if any, flexion of the operating table, and avoiding the use of the kidney rest in order to limit the risk of postoperative positional complications such as rhabdomyolysis [8]. The abdomen should be sterilely prepped in its entirety. If a Pfannenstiel incision is to be utilized for extraction, then the skin should be marked prior to patient positioning in order to ensure an optimal cosmetic result, and then prepped into the surgical field as well.

#### Abdominal entry and trocar placement

Among the different approaches to donor nephrectomy, the transperitoneal approach is the most utilized. The surgical procedure is begun by entry into the abdomen using a closed Veress needle technique, an optical trocar, or an open Hasson technique. A Cochrane review of randomized controlled trials concluded that the open technique is associated with a lower rate of failed entry into the abdomen, but found no difference in the likelihood of visceral or vascular injury between patients undergoing closed versus open techniques [9]. Consequently, the method of primary entry into the abdomen is left to the operative surgeon's discretion.

The sizes and positions of the trocars is surgeon dependent, however a classic triangular configuration with the camera trocar in the midline is the traditional method. For left renal procurement, we prefer to place an initial 5 mm trocar in a periumbilical location which is used as a working instrument trocar. After placement of this trocar, the abdominal contents are inspected and the position of the upper and lower poles of the kidney are identified. Next, a 5 mm trocar is placed at approximately the level of the renal hilum, slightly lateral to the midline in the left upper quadrant, and used as the camera trocar. The third 12 mm trocar is placed at the midclavicular line below the level of the lower pole of the kidney and used as a working instrument trocar.

### Initial mobilization

For a left-sided donor nephrectomy, the descending colon is mobilized along the white line of Toldt. The superficial peritoneal attachments between the colon and lateral sidewall should be released initially. Lateral renal attachments to the sidewall should not be released at this point, as this maneuver would result in medial mobilization of the kidney and interfere with hilar dissection. The colon is further dissected medially, exposing the proper plane between the colonic mesentery and Gerota's fascia. Recognition of this plane is important, in that inadvertent entry into the mesentery can lead to bleeding as well as mesenteric defects with potential for internal herniation. The dissection is carried cephalad towards the upper pole of the kidney. Extensive splenic mobilization is required to provide adequate exposure of the upper pole of the kidney.

The psoas muscle is exposed below the lower pole of the kidney. This muscle functions as an important landmark for locating the ureter. The ureter and gonadal vein are identified along the medial border of the psoas muscle (Figure 108.1). Care should be taken to avoid entering the psoas muscle fascia, which may lead to unnecessary bleeding or damage to the genitofemoral nerve. The ureter is dissected to the level of the iliac artery bifurcation. Meticulous care is taken to avoid ureteral devascularization. Following distal ureteral transection, the remaining blood supply to the ureter arises proximally from the renal artery, and therefore excessive dissection of the periureteral tissue is avoided. The ureter is not divided at this time. By gently elevating the ureter and lower pole of the kidney with an instrument, the medial border of the kidney is dissected in a cephalad direction to the level of the renal hilum. The correct plane of dissection lies medial to the gonadal vein. As the ureter and lower pole of the kidney are elevated, the gonadal vein can be traced towards the renal hilum (Figure 108.2). Exposure of the renal vein, adrenal vein, gonadal vein, and lumbar branch is performed after the colon has been fully mobilized medially (Figure 108.3). When both lateral traction of the kidney and medial traction of spleen are needed, placement of an accessory trocar

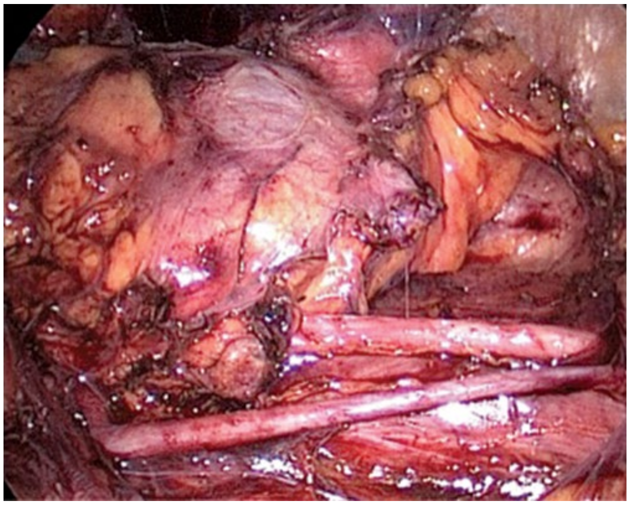

**Figure 108.1** Identification of the gonadal vein (medial) and ureter (lateral) on the psoas muscle inferior to the lower pole of the kidney.

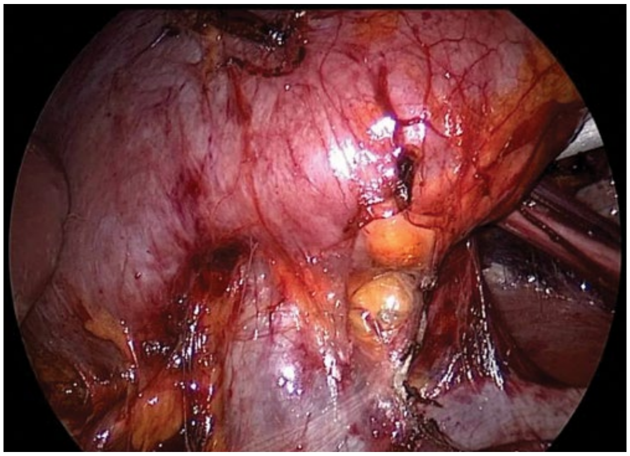

**Figure 108.2** Optimization of anterolateral retraction of the kidney and ureter using a laparoscopic instrument introduced through an accessory laparoscopic trocar.

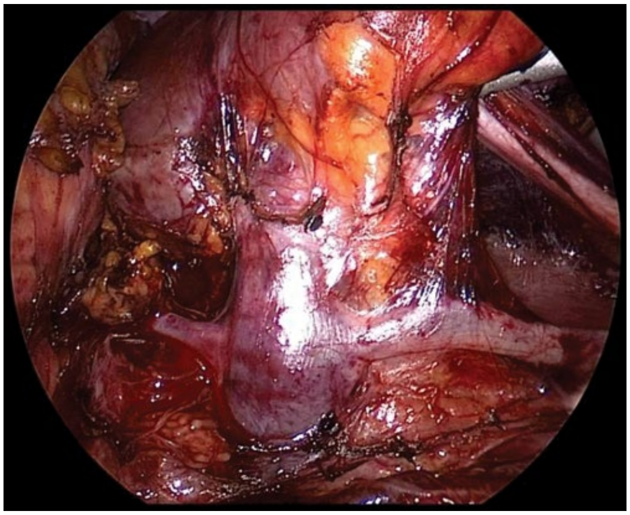

**Figure 108.3** Identification of the adrenal vein's ostium from the proximal, superior border of the left renal vein.

may be beneficial. This additional trocar can be introduced along the anterior axillary line at the inferior border of the kidney. A laparoscopic instrument can be introduced via this trocar to provide anterolateral retraction of the kidney so that the surgeon may use both working instruments to perform the hilar dissection.

### Hilar dissection

Once the kidney has been retracted anterolaterally, the gonadal vein is dissected at its insertion into the renal vein. The gonadal vein can be ligated and divided with a bipolar vessel-sealing device. Alternatively titanium or polymer clips can be utilized to ligate the vessel. The stump of the gonadal vein may serve as a handle for superior traction of the renal vein to help identify the lumbar vein and renal artery posteriorly. The adrenal vein is dissected at its insertion into the renal vein. The adrenal vein is ligated and divided with a bipolar vessel-sealing device or with clips. An advantage of a vessel-sealing device is that it eliminates the presence of clips that may interfere with subsequent placement of an endoscopic linear stapling device. The lumbar vein, when present, enters the renal vein posteriorly. This vein must be ligated and divided in order to identify the renal artery, which lies immediately posterior to the lumbar vein (Figure 108.4).

The renal vein is dissected from all surrounding perivascular tissues to a point medial to the adrenal vein stump. This maneuver provides maximal venous length for the vascular anastomosis. The renal artery is identified posterior to the renal vein and is dissected from the surrounding investing tissues. The renal artery must be carefully dissected in a retrograde fashion to its origin at the level of the aorta.

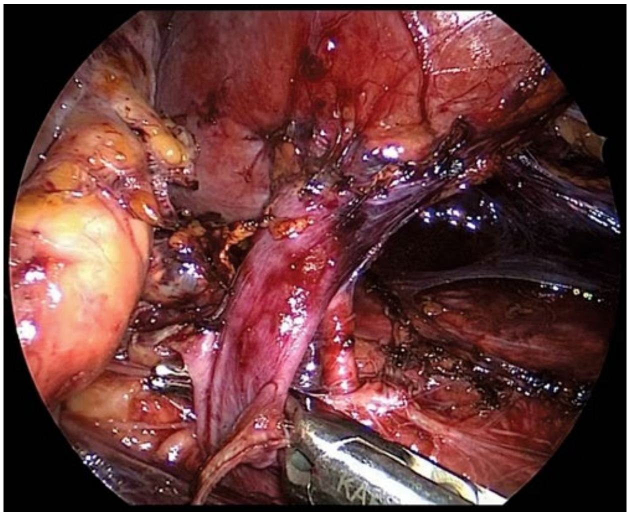

**Figure 108.4** Identification of the renal artery posterior and inferior to the renal vein and the divided stumps of the adrenal, gonadal, and lumbar veins.

### Dissection of the adrenal gland

After ligation and division of the adrenal vein, Gerota's fascia is entered along the anterior aspect of the upper pole of the kidney, exposing the renal capsule. With gentle displacement of the adrenal gland medially, meticulous dissection between the adrenal gland and the upper pole of the kidney is carried out. The use of a bipolar vessel-sealing device is beneficial in this area due to the highly vascular nature of the adrenal gland. If bleeding is encountered in this area, the application of gentle pressure is usually effective in obtaining hemostasis. In addition, renal artery branches to the upper pole of the kidney are not uncommonly encountered during this portion of the dissection, and one should be careful about inadvertent vascular injury. The upper pole of the kidney is released by dividing medial and superior attachments. The remaining posterior and lateral attachments of the kidney are released last. The kidney is rotated medially in order to expose the posterior surface of renal artery and vein. Any remaining perihilar tissue is dissected posteriorly. It is important to verify that all attachments to the kidney have been divided before hilar clamping.

### Specimen extraction incision

The specimen extraction incision is made prior to hilar clamping. A decision must be made as to whether the specimen will be extracted by lengthening an existing trocar incision site or via creation of a Pfannenstiel incision. A recent systematic review and meta-analysis comparing Pfannenstiel extraction versus extraction through an extended trocar site found no differences between cohorts in terms of incision length, morbidity, wound complications, or postoperative opioid consumption [10]. We routinely utilize both techniques depending on the preference of the patient and the recipient's transplant surgeon. Extraction through a periumbilical incision allows for rapid and facile utilization of an endoscopic TA linear stapling device (rather than a GIA linear stapling device) which may be preferable in cases where length of the renal vein may be lacking or in right-sided donor nephrectomy [11]. In this case, the periumbilical trocar incision should be lengthened to match the size of the kidney (generally 5–7 cm). A hand-access device can be placed to maintain pneumoperitoneum as a trocar is placed through the device. Alternatively, the surgeon's hand can be placed directly into the abdomen through this incision either with or without [12] the use of a hand-access device in order expedite extraction. In the case of a Pfannenstiel incision, a 5–7 cm is created and the fascia is incised in the midline to expose the peritoneum. A 15 mm trocar is placed through the peritoneum and a laparoscopic extraction bag is placed behind the kidney in order to elevate the kidney by providing lateral traction. Alternatively, the surgeon's hand can be placed directly into the abdomen as described for the periumbilical incision.

### Final preparations

At this point intraoperatively, final preparations are made in anticipation for hilar division and specimen extraction. The operating room staff should confirm that all appropriate equipment for specimen extraction and back table preparation are available in the room, including adequate staple reloads for the patient's hilum, an extra stapling device in the unlikely event of a stapler misfire, ice slush for rapid cooling of the specimen, and a completely furnished back table according to the transplant team's specifications. Ensuring the availability of all necessary components of the extraction will help minimize warm ischemia time.

Consultation should be performed with anesthesia to confirm adequate hydration and donor urine output prior to hilar ligation. If the patient has shown any signs of oliguria in the hour preceding this point in the case, it is best to wait for additional hydration prior to division of the renal hilum and specimen extraction.

The pneumoperitoneum created during laparoscopic surgery can have transient negative effects on urine output and renal function. This is cause for concern because low urine output in the donor may lead to delayed graft function in the recipient. Therefore certain measures during laparoscopic donor nephrectomy have been described to promote urine production and allograft function. Adequate hydration is mandatory, and many centers use loop or osmotic diuretics to promote a diuresis. Our preference is to administer one dose of 12.5 g of mannitol at time of the dissection of the gonadal and adrenal veins, and an additional 12.5 g of mannitol during renal artery dissection. Other groups have described the use of other combinations of mannitol and furosemide, as well as continuous infusions of mannitol and dopamine during laparoscopic donor nephrectomy.

The use of systemic heparin to prevent vascular thrombosis during donor nephrectomy remains controversial. An intravenous dose of up to 5000 U, with or without protamine reversal (up to 50 mg IV), is routinely advocated by many centers [13]. However, the literature suggests that the use of heparin, given either alone or with protamine reversal after the graft is removed, does not offer any clinical benefit in terms of preventing graft thrombosis or improving allograft function [14–16]. Some groups have abandoned this practice altogether because of the potential for exacerbating hemorrhagic complications.

Finally, in order to maintain adequate arterial blood flow during renal artery dissection, some surgeons advocate the topical application of papaverine (30 mg/ml solution, 10–20 ml total) to prevent arterial vasospasm.

### Hilar division

The ureter may then be ligated and divided at the level of the iliac vessels in order to maximize ureteral length to facilitate transplantation (Figure 108.5). A clip is placed on the ureter distally and the ureter is divided proximally. In a well-hydrated patient, urine is usually seen emanating from the proximal end of the ureter after transection.

An endoscopic TA linear stapling device is used to ligate the renal artery at its origin from the aorta. The artery is immediately divided lateral to the staple line using laparoscopic scissors. Length of the renal artery may be maximized by medial rotation of the kidney and application of the stapling device from a posterior approach (Figure 108.6). Alternatively, an endoscopic GIA linear stapling device can be used to the ligate and transect the renal artery, however this maneuver may compromise the length of the renal artery, as the staple line on the specimen side will need to be excised prior to initiating the vascular anastomosis. Hem-o-lok® ligating clips (Teleflex Medical, Bannockburn, IL, USA) are contraindicated for use in ligating the renal artery during laparoscopic nephrectomy in living donor patients. The manufacturers of the Hem-o-lok clip issued a memo in April 2006 stating that the Hem-o-lok ligating clips may become dislodged following ligation of the renal artery during laparoscopic donor nephrectomy which can lead to massive hemorrhage, open conversion, delayed hemorrhage requiring re-exploration, and even death [17, 18].

After division of the artery, an endoscopic TA linear stapling device is placed from an anterior approach and used to ligate the renal vein medial to the adrenal and gonadal branches (Figure 108.7). The vein is then divided lateral to the staple line using laparoscopic scissors. Once the specimen is free, it is either manually extracted through the planned extraction site or it is placed in a

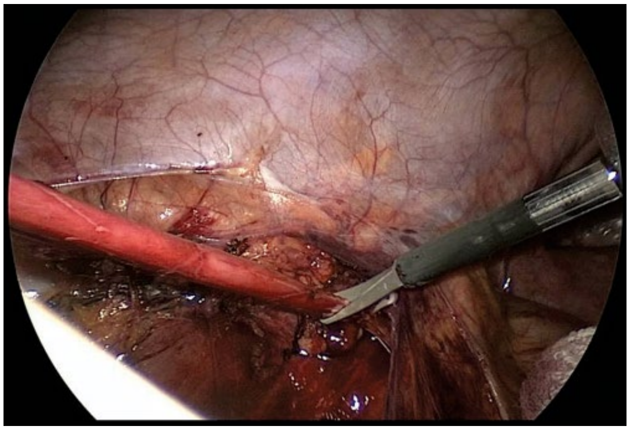

**Figure 108.5** Division of the ureter just proximal to the level of the iliac vessels.

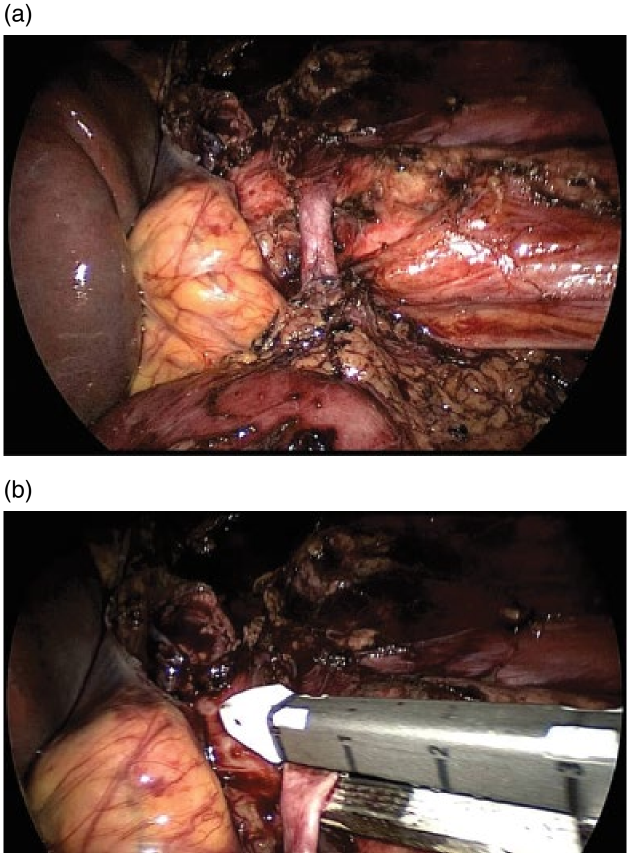

**Figure 108.6** (a) Renal artery visualization and (b) application of the endoscopic TA linear stapling device via a posterior approach.

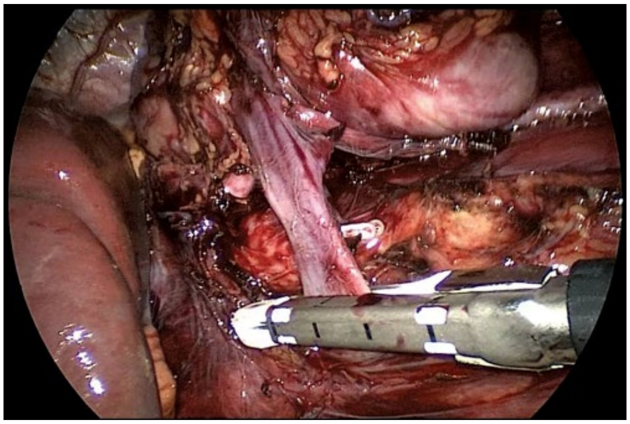

**Figure 108.7** Application of the endoscopic TA linear stapling device on the renal vein from an anterior approach.

laparoscopic extraction bag. The kidney is extracted and placed on ice. The kidney is then passed to the awaiting transplant surgical team.

Although exceedingly rare, stapler malfunctions have been reported. In such situations, an additional 12 mm trocar may be used to place a second stapling device. If possible, a second row of staples is applied across the bleeding vessel more proximally. When sufficient vessel length does not permit this salvage method, open conversion may be required.

### Closure

The extraction site fascia should be closed in standard fashion using either a running or interrupted fashion according to surgeon preference. After the extraction site fascia is closed, the abdomen is reinsufflated to 5 mmHg and the peritoneal cavity is laparoscopically inspected for bleeding or visceral injury. After inspection, all trocars are removed under direct vision and closure of all trocar sites 10 mm or larger is performed with a fascial closure device. Finally, the pneumoperitoneum is evacuated and the skin incisions are closed.

## Right laparoscopic donor nephrectomy

### Abdominal entry and trocar placement

Although the positioning and procedure for a right-sided donor nephrectomy is similar to a left-sided donor nephrectomy, some of the differences require clarification. A 12 mm trocar is inserted at the umbilicus and is used as the primary working trocar. A 5 mm camera trocar is placed slightly to the right of midline, approximately 2 cm below the xiphoid process. A 5 mm trocar is placed at the midclavicular line, and below the level of the umbilicus. An accessory 5 mm trocar is placed along the anterior axillary line below the costal margin and is used for liver retraction.

### Initial mobilization

The triangular ligament is incised to release the right lobe of the liver from the sidewall. A liver retractor is placed through the lateral subcostal trocar, and the liver is retracted superiorly to expose the upper pole of the kidney.

The right colon is reflected medially and a Kocher maneuver is performed to mobilize the duodenum medially. The peritoneal layer overlying Gerota's fascia is incised in a cephalad direction medially, and then in a lateral direction after reaching the upper pole of the kidney. The psoas muscle is exposed below the lower pole of the kidney. The ureter and gonadal vein are identified along the medial border of the psoas muscle. The ureter is dissected to the level of the iliac artery bifurcation. The ureter is not divided at this time. By gently elevating the ureter and lower pole of the kidney with an instrument, the medial border of the kidney is dissected in a cephalad direction to the level of the renal hilum. The correct plane of dissection lies lateral to the gonadal vein.

Gerota's fascia is entered along the anterior aspect of the upper pole, exposing the renal capsule. Meticulous dissection between the adrenal gland and the upper pole of the kidney is carried out.

#### Hilar dissection

The right adrenal vein enters directly into the inferior vena cava and is not dissected during a right-sided donor nephrectomy. The inferior border of the renal vein must be found by tracing the lateral aspect of the inferior vena cava to the ostium of the renal vein. Because of the anatomic limitations of a short right renal vein, a fervent attempt is made to salvage as much renal vein length as possible. The renal artery can be reliably identified posterior and inferior to the renal vein. Ligation and division of the ureter and renal hilum, and extraction of the specimen, is performed as described previously for the left-sided procedure.

### Hand-assisted laparoscopic donor nephrectomy

Hand-assisted laparoscopy has transformed the field of operative urology over the past decade, and its applications have been applied to a variety of procedures since its introduction. In this technique, the surgeon's nondominant hand is introduced into the surgical field through a hand-access device while the dominant hand uses laparoscopic instruments that are introduced through standard laparoscopic trocars. The nondominant hand facilitates dissection by providing the surgeon with tactile feedback and manual retraction, while additionally allowing prompt hemostasis, vascular control, and rapid specimen extraction.

### Laparoendoscopic single-site donor nephrectomy

Laparoendoscopic single-site (LESS) surgery has been adopted for a variety of urologic procedures and represents the next step in the evolution of conventional laparoscopic surgery. This surgery is performed through a single small skin incision, often partially concealed at the umbilicus. Several studies have shown that LESS living donor nephrectomy has been associated with decreased postoperative pain and better postoperative cosmesis, while providing equivalent graft outcomes when compared to the conventional laparoscopic approach. This technique, however, is far from the new standard of care due to the unique challenges posed by single-site surgery including problems with instrument clashing, difficulty with triangulation, and poor ergonomics.

There are several different techniques for performing LESS donor nephrectomy. The most commonly used technique utilizes a 5 cm periumbilical incision. The abdomen is entered through a vertical anterior rectus fasciotomy. The GelPOINT® device (Applied Medical Systems, Rancho Santa Margarita, CA, USA) is inserted into the abdomen with three triangulated trocars preplaced into the device (Figure 108.8). Typically, two 5–10 mm and one 15 mm trocars are used. If a right-sided LESS donor nephrectomy is being performed, a fourth trocar is placed through the GelPOINT® to allow for the use of a liver retractor. Pneumoperitoneum is then achieved. The remainder of the procedure is performed similar to what has been described above for conventional laparoscopic donor nephrectomy.

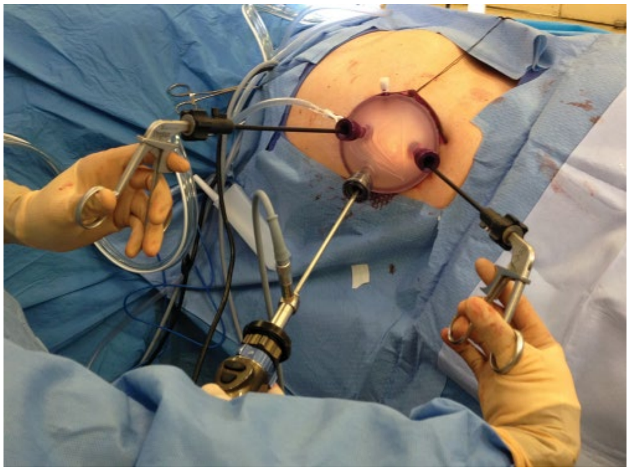

**Figure 108.8** Laparoendoscopic single-site (LESS) device and instrumentation for donor nephrectomy.

Once the renal hilum and all of the perinephric attachments have been carefully dissected, the gonadal vein and ureter are transected at the level of the iliac vessels, and the renal artery and vein are then ligated and transected. A laparoscopic extraction bag is then introduced to capture the kidney and the specimen is removed by removing the gel cap of the single-site device.

### Robot-assisted laparoscopic donor nephrectomy

Robot-assisted laparoscopic surgery has become widely accepted in urologic surgery as a revolutionary advance in operative technique due to the improved three-dimensional visualization of the operative field and the degrees of freedom offered by the robotic instruments. Several small studies have confirmed that robot-assisted laparoscopic donor nephrectomy is a viable, safe, and effective surgical technique. However, further studies are necessary to determine if robot-assisted surgery provides any advantages over traditional laparoscopic techniques.

## Postoperative management

### Hospital course

The orogastric tube is removed at the completion of the procedure. The patient is transferred from the recovery room to a regular room overnight. A Foley catheter is maintained overnight to permit strict monitoring of urine output. A chemistry panel and complete blood count are obtained in the recovery room and on the first postoperative day. The Foley catheter is removed on the first postoperative day. A clear liquid diet is started on the day of surgery and the diet is advanced as tolerated.

Most patients are discharged home with opioid pain control and a bowel regimen on the first postoperative day. Patients are generally seen for a routine evaluation seven days postoperatively. Unless abnormalities were noted during the hospitalization, there is no need for laboratory studies at this visit. Patients are advised to follow-up with either their primary care physician or transplant nephrologist at three months postoperatively for blood pressure measurement and routine laboratory studies. All donors should be advised to remain compliant with yearly routine annual follow-up with their primary care physician in order to monitor their blood pressure, renal function, and urine studies. Patients should also be counseled on avoiding chronic use of nephrotoxic medications (e.g. nonsteroidal anti-inflammatory drugs [NSAIDs]). It may be beneficial to arrange for donors to meet with a nutritionist postoperatively in order to help educate them on renal healthy diets and encourage healthy eating habits.

### Pain control

In most instances, we advocate the utilization of intravenous ketorolac in a scheduled fashion for the first 24 hours postoperatively as it has been demonstrated to reduce pain and opioid requirement postoperatively, shorten length of stay and quicken the return of bowel function postoperatively [19, 20]. It should be noted that the use of ketorolac in patients following donor nephrectomy is somewhat controversial due to reports that patients receiving the drug exhibit a lower creatinine clearance in the immediate postoperative period, but these differences do not persist at long-term follow-up [19]. After completion of 24 hours of scheduled intravenous ketorolac, most patients are discharged with a short supply of oral opioid medication (e.g. tramadol). They are further advised to avoid the use of NSAIDs in the future in order to protect their renal function.

### Complications

The overall postoperative complication rate following laparoscopic donor nephrectomy in large, contemporary series has been estimated at approximately 3.4–10.3% and primarily low grade in nature (e.g. wound infection or minor wound complications) [21–23]. The open conversion rate in most contemporary series is very low and has reported to range from 0.2% to 1.8% [21, 23–25]. Moreover, these reports of complications and conversion rates may actually represent slight overestimations today as many of these large case series report that the majority of conversion or complications occurred early in the laparoscopic donor nephrectomy experience (first 100–150 cases) [6, 14, 23]. Consequently, the rate of complications or open conversion can be reasonably believed to be even lower today.

## Conclusions

Laparoscopic donor nephrectomy has been demonstrated to be a safe alternative to open renal donation. Consequently, it is considered the standard of care at most transplant centers today. The reduced pain and opioid requirement, shorter convalescence, and improved cosmesis afforded by laparoscopic donor nephrectomy is likely partially responsible for reducing barriers to kidney donation and the increasing acceptance and performance of living donor nephrectomy with time.

## Introduction

The prevalence of chronic kidney disease (CKD) is rising along with increasing life expectancy. There has been a 30% increase in the prevalence of CKD in the United States in the last decade [1]. Similar data from developing countries such as India are scarce, but even conservative estimates reveal an age-adjusted incidence of 229 persons per million [2]. The numbers of endstage renal disease (ESRD) cases, and with that the number of patients waiting for a transplant, are increasing. Among the available methods of renal replacement therapy, kidney transplantation is associated with the best quality of life, best survival rates, and thus remains the treatment of choice for late stages of CKD [3].

Open surgery has been the gold standard for kidney transplant from the beginning and Carrel's technique of vascular anastomosis has been in use for over a hundred years. Although the introduction of minimally invasive techniques has completely transformed other surgical specialties, kidney recipient surgery has seen little change since its inception.

In recent years, the indications for minimally invasive surgery have expanded with the increasing use of surgical robots, and the field of kidney transplantation has not remained untouched. Evidence-based development of robotic kidney transplantation (RKT) in the last few years has opened a new frontier in recipient surgery. Reduction in perioperative complications remains a priority in frail, immunocompromised kidney recipients, who thus remain the ideal candidates for minimally invasive surgery. Obese transplant recipients in particular are a surgical challenge. Obesity leads to longer waiting times for transplant, higher risks of surgical site infections, and increased complications. In severe cases, such patients have been denied the opportunity for transplant in some centers. Early results of RKT have shown shorter convalescence times, less perioperative morbidity, and better cosmesis. In addition to these obvious benefits, RKT has been shown to be associated with decreased surgical site infections, and lower incidence of lymphoceles and vascular complications. This chapter reviews the development, technique, and current status of RKT.

## A brief history of robotic kidney transplantation

### History of laparoscopic kidney transplantation

The use of a surgical robot in kidney transplant was first described in a case of deceased donor transplant by Hoznek et al., from France, in 2001 [4]. The robot was used for vascular anastomosis and ureteroneocystostomy after making an open incision. Although the ability of the da Vinci® surgical robot (Intuitive Surgical, Sunnyvale, CA, USA) to handle fine sutures, such as 6-0 polydioxanone and 5-0 polypropylene, was demonstrated in this case, as was the ability of robotic instruments in dissection, lack of haptic feedback required the bedside assistant to follow the suture. Little enthusiasm was shown for this procedure in the next decade, until Antonio Rosales from Spain reported the first laparoscopic transplant in 2009. In this surgery, the kidney was introduced into the abdomen through a Pfannenstiel incision and the anastomosis was performed laparoscopically in 53 minutes. The cold ischemia time was 182 minutes [5]. Soon, Modi et al. from India described the procedure in four patients, in a deceased donor program [6]. They used the left kidney from the deceased donor for the laparoscopic procedure. A Carrel's patch was

Companion website: www.wiley.com/go/smith/textbookofendourology

used to carry out a wide arterial anastomosis. The mean anastomosis time for laparoscopic procedure was reported as 65 minutes, which is not significantly longer than that for open surgery. More importantly, they reported equivalent renal function outcomes at 1 year, six months, and 1 year following surgery, for both open and laparoscopic recipients. The same group reported a series of 72 more cases in the following years [7]. The rewarming time (time taken after the graft is placed in the recipient until the graft is revascularized) was significantly longer in the laparoscopic group compared to the open group (60.3 vs. 30.3 minutes). Even though the estimated glomerular filtration rate (eGFR) at 7 and 30 days after transplant was lower in the laparoscopic group, the graft survival was excellent at six months. There was no difference in graft survival at 3, 6, 12, and 18 months postoperatively. Interestingly, since the graft was free-floating in the peritoneal cavity, there were two cases of torsion of graft leading to graft loss. The technique was subsequently modified to fix the graft using a peritoneal flap. Even as this study proved the feasibility of minimally invasive transplant, the operation remained extremely challenging. As a result, it did not see widespread adoption.

## Early development of robotic kidney transplant

The first RKT was reported from the University of Illinois at Chicago by Giulianotti et al. in 2010 [8]. A 7 cm periumbilical incision, and a hand-assist device was used for this procedure, in a morbidly obese patient with a body mass index (BMI) of 41 kg/m$^2$. Total operative time was 223 minutes and warm ischemia time was 50 minutes. The blood loss was less than 50 ml. Soon afterwards, the first case from Europe was reported by Boggi et al. A Pfannenstiel incision was used in this case, through which the ureterovesical anastomosis was performed in an open fashion. The operative time was 154 minutes and warm ischemia time 51 minutes [9].

The Chicago group subsequently reported RKT case series of 28 obese recipients (BMI 42.6 ± 7.8 kg/m$^2$). In the later part of the series, robot-assisted clamping was used instead of the hand-assist device used in the initial cases [10]. For the preparation of transplant bed and vascular anastomosis, a right flank position was used. For the ureteroneocystostomy, the patient has to be repositioned and the robot had to be redocked. The graft was left intraperitoneal and for a renal biopsy, when required, laparoscopy had to be used. According to this study, although there was no difference in cold or warm ischemia times between open kidney transplant (OKT) and RKT groups (RKT: 2.8 and 47.7 minutes; controls: 2.0 and 49.2 minutes; $P \geq 0.48$), the creatinine at discharge was higher in the RKT group than in the OKT group (2.0 mg/dl vs. 1.4 mg/dl; $P = 0.04$). The higher creatinine at discharge may be explained by poor allograft perfusion due to pneumoperitoneum [11]. The renal function at six months postoperatively was similar (serum creatinine 1.5 ± 0.4 mg/dl vs.1.6 ± 0.6 mg/dl; $P = 0.47$). Surgical site infections were found to be significantly less in the RKT group than in the OKT group (0/28 (0%) in RKT vs. 8/28 (28.6%) in OKT; $P = 0.004$).

These early experiences with minimally invasive transplant were pioneering, but critical analysis showed a slower return of graft function postoperatively. This was probably a result of increased anastomosis time, with the graft at body temperature, and lack of methods for intracorporeal cooling of the graft during anastomosis, which may cause slower return of graft function postoperatively. This effect could have been compounded by longer anastomosis times during the learning curve.

## Development of the Vattikuti Urology Institute RKT technique with regional hypothermia

The experimental studies by Wickham showed that the ideal temperature for maximal reno-protection during nonvascularized phase was around 20 °C [12]. Regional hypothermia using ice slush introduced into the pelvis was evaluated in >300 robotic prostatectomy patients at Vattikuti Urological Institute (VUI) in Detroit, USA. The ice slush was introduced through a GelPOINT® device (Applied Medical Inc., Rancho Santa Margarita, CA, USA). It was demonstrated that an average pelvic temperature of 15.8 °C could be achieved within 15 minutes of icing, with no change in core body temperature [13]. This finding led to the concept of regional hypothermia for RKT, which was then put into practice by collaboration between the VUI team and the Medanta team from India. The new procedure was developed according to IDEAL (idea, development, exploration, assessment, long-term follow-up) guidelines [14]. Phase 0 IDEAL studies were conducted in two fresh cadavers. This phase led to standardization of patient positioning, port placement, docking of the robot, and the choice of instruments and sutures. In this phase, the use of a GelPOINT device to introduce the kidney and ice slush into the pelvis was also established. The standardized pelvic docking also eliminated the need to reposition the robot for urethrovesical anastomosis, as was needed in previously reported efforts at robotic transplantation [15]. Phase 0 was followed by phase 1 study, during which seven patients underwent RKT with regional hypothermia by the combined VUI and Medanta team in India in January 2013. In this phase a mean kidney surface temperature of 22.5 °C could be achieved using regional hypothermia, with no patient developing systemic hypothermia. The mean arterial, venous, and ureterovesical anastomosis times were 14.4, 14, and 23.4 minutes, respectively. The mean rewarming time was 51.4 minutes, while the mean warm ischemia time was 2 minutes. Mean serum creatinine on postoperative days 1 and 7 were 2.2 mg/dl and 1.2 mg/dl, respectively. One patient required re-exploration due to increased drain output, but no specific bleeding point could be detected on exploration.

Next phase of the development of RKT consisted of 43 patients. Mean operative and console times were 214.1 ± 39.8 (156–293) and 135.4 ± 31.2 (94–201) minutes, respectively. Mean warm ischemia, rewarming, and arterial and venous anastomosis times were 2.4 ± 1.1 (1.5–6.0), 46.6 ± 9.3 (27–66), 12.0 ± 2.6 (7–17), and 13.4 ± 3.4 (8–21) minutes, respectively. The anastomosis times decreased in this phase compared to the phase 1 study. Mean intraoperative renal surface temperature was 20.3 ± 2.9 °C (14.5–27.8) and the mean blood loss was 151.7 ± 103.5 (50–450) ml. The average incision length was 6.1 ± 0.5 (5.4–7.1) cm. Mean serum creatinine at discharge was 1.3 ± 0.6 (0.8–3.1) mg/dl. No patient experienced delayed graft function, vascular or urine leaks, wound complications, or wound infections. There was no peri-graft collection on computed tomography in any patient at three months. No further complications were recorded at six months follow-up. One patient died at 1.5 months due to acute congestive heart failure secondary to a cardiac condition [11]. Presently, the evolution of RKT is in the IDEAL phase 3, and is being compared with OKT.

## Preoperative preparation of patients for RKT

Standard pretransplant medical evaluation includes assessment of the recipient for infectious and immunological risks, and malignancy. Modifiable risk factors for morbidity such as coronary artery disease, hypertension, and diabetes mellitus are then optimized. Patient education for relevant lifestyle modifications such as smoking cessation, risks of immunosuppression, and medication compliance is important. Surgical risk assessment is then done for RKT which includes evaluation for peripheral vascular disease and obesity. Obesity is an independent risk factor for surgical site infections [16]. The indications and contraindications for RKT are listed in Boxes 109.1 and 109.2.

**Box 109.1 Indications (standard for any kidney transplant).**

a) Irreversible kidney disease, defined as:
   i) CKD with glomerular filtration rate <20 ml/min
   ii) CKD with symptomatic uremia
   iii) CKD requiring dialysis
b) Anticipated ESRD, as defined as (a), within the next 12 months (preemptive transplant)
c) Absence of malignancy and/or active infection
d) Availability of appropriate kidney donor

CKD, chronic kidney disease.

**Box 109.2 Contraindications for robotic kidney transplantation in potential recipients otherwise suitable for kidney transplantation.**

- Significant atherosclerotic disease of the iliac vessels (>30% blockage)
- Previous major abdominal surgery with high suspicion for intra-abdominal adhesions (relative)
- Simultaneous dual or multiple organ transplant (relative)

## Step-by-step technique (Video 109.1)

### Step 1: Preparation of GelPOINT device

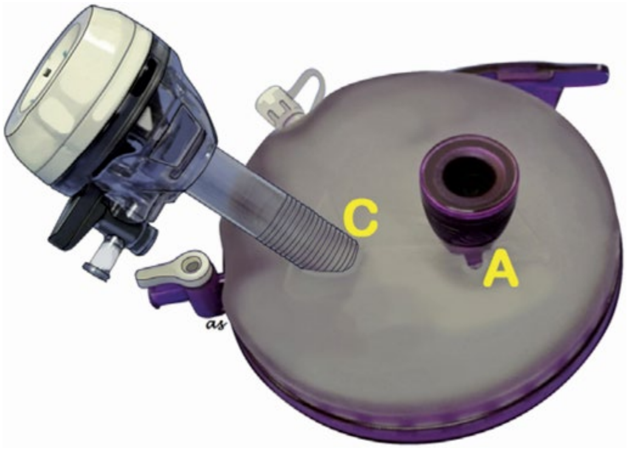

**Figure 109.1** Preparation of GelSeal cap, with a 12 mm camera port (C) and a 5 mm assistant port (A). *Source:* Menon M, Sood A, Bhandari M et al. Robotic kidney transplantation with regional hypothermia: a step-by-step description of the Vattikuti Urology Institute-Medanta Technique (IDEA phase 2a). *Eur Urol* 2014;65(5):991–1000. Reproduced with permission of Elsevier.

The GelPOINT device is placed through a 5–6 cm vertical midline incision curving around the umbilicus. The incision could be predominantly extended above the umbilicus in smaller patients. The GelSeal® cap is prepared with a 12 mm camera port and a 5 mm assistant port placed through it as shown in Figure 109.1. This 5 mm port will be the assistant's port. Optimal positioning of these ports into the cap is important, as placing these two ports too close to each other may lead to restriction of the assistant’s movement by the camera arm, and may hinder proper suctioning.

### Step 2: Port placement

After general anaesthesia and catheterization, with the patient in supine position, a 4–5 cm midline periumbilical incision is made for the GelPOINT device. The previously prepared GelPOINT device is placed through this incision. Pneumoperitoneum of 15 mmHg is created through this port. The rest of the port placement is identical to that for robotic prostatectomy (two 8 mm robotic ports along the left and right paramedian lines below the level of the umbilicus, a third 8 mm robotic port lateral to the left anterior axillary line just below the level of umbilicus, and a 12 mm assistant port along the right anterior axillary line) (Figure 109.2). For the da Vinci Xi robot, all 8 mm ports can be created in a single line, just above the level of the umbilicus, while the assistant port remains the same as described above.

### Step 3: Patient positioning

The patient is placed in a modified lithotomy as for robotic prostatectomy [17] if the Si or older models of da Vinci are being used. For the da Vinci Xi system, the patient can be placed supine, and in a 15–20° Trendelenburg position.

### Step 4: Docking of the robot

The robot may be docked between the patient’s legs if patient is in modified lithotomy. For the da Vinci Xi system, the patient can be supine, and the robot is docked from the side, usually the left side. The boom of the patient cart can then be adjusted to achieve the same position of robotic arms as in the standard docking of the previous surgical robots.

### Step 5: Instruments used

Authors find a “30 down” vision beneficial for this part of the procedure. Fenestrated bipolar forceps, and monopolar curved scissors are preferred instruments for preparation of the transplant bed. The peritoneum over the iliac vessels is incised, and the external iliac vessels are skeletonized from the level of the common iliac artery bifurcation to the inguinal ligament. With experience, it may become possible to reduce to minimal dissection, just freeing sufficient length for clamp and anastomosis. Some external iliac vein tributaries may, at times, need clipping and division to free up sufficient length (Figure 109.3).

The peritoneum distal to cecum is horizontally divided, starting from the center of the previously incised peritoneum over the iliac vessels. The proximal and distal flaps of the peritoneum are raised and used later to extraperitonealize and fix the graft.

Vision is changed to “30 up” and the urinary bladder is dropped from the anterior abdominal wall to the pubic

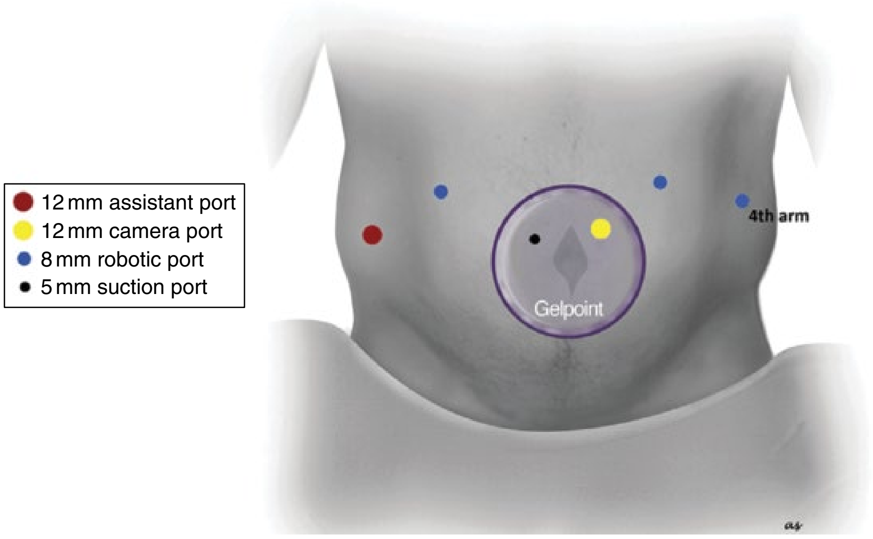

**Figure 109.2** Port placement. *Source:* Menon M, Sood A, Bhandari M et al. Robotic kidney transplantation with regional hypothermia: a step-by-step description of the Vattikuti Urology Institute-Medanta Technique (IDEA phase 2a). *Eur Urol* 2014;65(5):991–1000. Reproduced with permission of Elsevier.

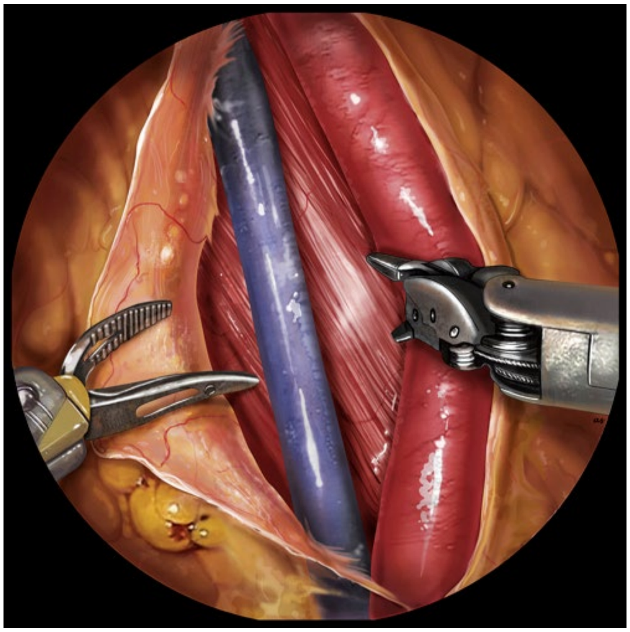

**Figure 109.3** Preparation of the iliac vessels (graft bed preparation). *Source:* Menon M, Sood A, Bhandari M et al. Robotic kidney transplantation with regional hypothermia: a step-by-step description of the Vattikuti Urology Institute-Medanta Technique (IDEA phase 2a). *Eur Urol* 2014;65(5):991–1000. symphysis. After filling the bladder with 200 ml of normal saline, a site is prepared for ureterovesical anastomosis on the anterosuperior aspect of the bladder ipsilaterally (Figure 109.4). A detrusor tunnel is made at the proximal end of the selected ureterovesicostomy site to give sufficient submucosal length.

## Step 6: Preparation of the graft kidney jacket

After harvesting, the graft kidney is enclosed in a jacket made of surgical gauze. Some ice slush is also enclosed inside the graft jacket around the graft (Figure 109.5). A hole is made in the jacket medially, which allows renal vessels to be brought out. The authors leave a long silk suture marker at the upper pole for correct orientation of the graft to identify the two ends when graft has been placed inside the peritoneal cavity. The jacket helps in maintaining intracorporeal cooling, as well as enabling holding and moving the graft without trauma to the graft. It also keeps the hilar fat retracted, thus presenting the vessels for easier anastomosis.

## Step 7: Regional hypothermia

After undocking of the robotic camera arm, and removal of the GelSeal cap, Toomey syringes with their front end cut off (Figure 109.6) are used to introduce 200–250 ml of ice slush through the GelPOINT device. The ice slush is placed on the pelvic bed, over the dropped bladder flap (Figure 109.7). Additional ice slush may be delivered onto the graft, immediately after the graft's introduction as well as between venous and arterial anastomosis, to achieve uniform cooling and prolonged effect (Figure 109.8).

## Step 8: Vascular anastomoses

The external iliac vein is now isolated both proximally and distally, with bulldog clamps introduced through the assistant port (Figure 109.9). Appropriate length venotomy is then made with scissors, and the external iliac vein flushed with heparinized saline. The external iliac

Reproduced with permission of Elsevier.

vein is anastomosed to the graft renal vein using Gore-Tex® 5-0 CV-6 suture with a 9 mm needle (Figure 109.10). The authors prefer this suture because of its many useful properties. It is a microporous, nonabsorbable, monofilament suture made of expanded polytetrafluoroethylene. It is soft and supple with no memory, and has sufficient strength for robotic handling. Needles at both ends are used, one each for venous and arterial anastomosis. The appropriate suture length is 15 cm for arterial and 18 cm for venous anastomosis. Black Diamond™ forceps are used in the nondominant hand similar to the use of DeBakey forceps in open surgery, to spread and handle vascular tissue for precise suturing, while a large robotic needle driver is used in the dominant hand during the anastomosis. An end-to-side anastomosis of the graft renal vein to the clamped external iliac vein is then performed. The authors prefer to start the anastomosis at the distal end, completing the posterior wall in a continuous manner. After turning the corner, and before proceeding to the anterior wall, a knot is tied.

A ureteric catheter introduced through the assistant port is used to flush the vein with heparinized saline before the final suture is pulled and tied. The graft renal vein is now clamped, and the clamps on the external iliac vein are removed. The bulldog clamps removed from the external iliac vein are applied to the proximal and distal end of the dissected external iliac artery. Robotic Snapfit® or a Pott's scissor is used to make a small arteriotomy, before using a 3.6 mm vascular punch inserted through GelPOINT device to make an adequate rounded opening (Figure 109.11). The authors have devised a long, metallic laparoscopic arterial punch for this step, as the standard commercially available arterial punches are limited in length, and it may not be possible to reach the external iliac artery from the GelPOINT device with them, especially in obese patients. An end-to-side anastomosis of the graft renal artery is done with external iliac artery using a technique similar to venous anastomosis (Figure 109.12).

The graft renal artery is now clamped, and the distal bulldog clamp on the external iliac artery removed to check for the integrity of the arterial anastomosis with the backflow from the distal external iliac artery. A major bleed can be tackled by taking extra sutures at this point. If there is no significant leak, the proximal bulldog clamp is removed from the external iliac artery to restore the flow continuity of the external iliac artery. Minor bleeding may be controlled by using Surgicel® over the bleeding point. The graft is then perfused by removing all of the clamps.

### Step 9: Cutting of gauze jacket and retroperitonealization of the graft

Scissors are used to cut the gauze jacket, which allows for visual inspection of the graft for color and turgidity. The graft jacket is now released, cutting it from its hilar opening proximally and distally to bare the graft and allow its visual inspection for color and turgidity. The graft is then flipped back into the right iliac fossa by turning it through 180° around the iliac vessels. This also allows for inspection of the other side of the anastomosis. The graft is then retroperitonialized by bringing the previously created proximal and distal peritoneal flaps over the graft, and using Hem-o-lok clips to keep them in place. The pneumoperitoneum is dropped to 8–10 mmHg at this stage to reduce its effect on graft perfusion.

### Step 10: Ureterovesicostomy

The ureter is brought out beneath the vas and the detrusor tunnel. A 4-0 polydiaxonone (PDS) or polyglactin (Vicryl) suture is used for the ureterovesical anastomosis. After completing the posterior layer, a 6 Fr, 16 cm double-J stent is placed before proceeding to the anterior layer of the anastomosis. A 3-0 barbed suture (3-0 V-Loc®) is used for detrusorrhaphy after the anastomosis is complete (Figure 109.13).

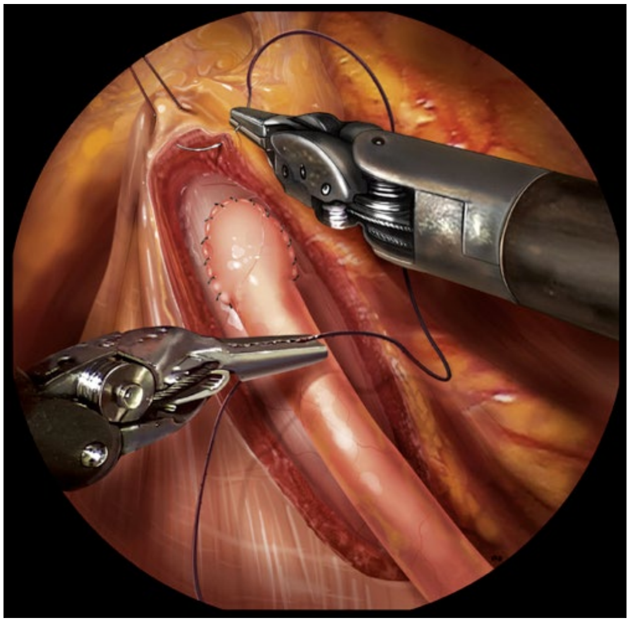

**Figure 109.13** A 3-0 barbed suture is used for detrusorrhapy after ureterovesical anastomosis. *Source:* Menon M, Sood A, Bhandari M et al. Robotic kidney transplantation with regional hypothermia: a step-by-step description of the Vattikuti Urology Institute-Medanta Technique (IDEA phase 2a). *Eur Urol* 2014;65(5):991–1000. Reproduced with permission of Elsevier.

### Step 11: Drain placement, undocking, and on-table Doppler

A flat drain is introduced through the fourth arm port, and is kept anterior to the urinary bladder. A 24 Fr drain is placed in the pouch of Douglas via the right 12 mm assistant port. The robot is then undocked and the ports are removed under vision before closing the wounds. It is possible that the anatomical relationship of the graft vessels and the external iliac vessels may change after pneumoperitoneum has been stopped, risking kinking of vessels. The authors routinely do an on-table vascular Doppler of the graft to confirm its vascularity before shifting the patient out to the transplant intensive care unit.

Prophylaxis for deep vein thrombosis is used as a part of protocol for any pelvic surgery. Postoperatively, calf exercises and early ambulation are encouraged.

## Evaluation of learning curve

The learning curve of RKT depends on two major factors: the experience of the surgeon in robotic surgery and their experience in kidney transplantation. Studying the learning curve is important not only to ensure the safety of the procedure during adoption at a new center, but also for appropriate timing of surgical trials.

The LC of RKT has recently been studied using the cumulative summation methodology, by comparing an established RKT center with a center which recently adopted this procedure. In this study, using target values derived from the established RKT center, it was found that the LC at the adopting center is short, with improving skill up to 20–25 cases. The functional outcomes were comparable at the two centers, with no increased complication rates during adoption [18]. The effect of robotic training and open transplant experience has previously been studied using target values derived from OKT [19]. This study showed that no learning curve existed for a surgeon who was experienced in, and actively performing robotic surgery as well as OKT. For a surgeon with limited robotic surgery experience but extensive OKT experience, a definite learning curve existed for all the steps (i.e. 3 cases for competency in graft function, 9–12 cases for venous and arterial anastomoses, 11 cases for rewarming times, and beyond 14 cases for ureterovesical anastomosis). For a surgeon with extensive robotic experience but not actively performing OKT, competency was attained in six cases, with a learning curve existing only for the ureterovesical anastomosis step.

Importantly, graft function was not adversely affected by either the lack of robotic training or kidney transplant experience.

## Renal function outcomes

The renal function outcomes are similar with OKT and RKT. The authors recently compared 125 RKT and 543 OKT patients over 3 years (unpublished data), and found no difference in fall of serum creatinine at discharge, as well as at three and six months after surgery. The mean creatinine at discharge was 1.2 mg/dl in RKT, compared to 1.3 mg/dl in OKT patients ($P < 0.71$). Delayed graft function was seen in 1.6% (2/125) patients in the RKT group, compared to 3.13% (17/543) in the OKT group ($P > 0.05$). The data comparing RKT versus OKT found no significant difference in graft survival as well as patient survival.

## Complications

RKT uses a smaller incision than OKT (6.1 cm vs. 15.6 cm, $P = 0.001$). A conference abstract on unpublished IDEAL stage 2b/3 studies indicated that the postoperative pain scores (visual analog scale [VAS] scores at 24 hours; $P < 0.001$), as well as analgesic requirements (16.9 vs. 29.7 mg morphine-equivalent patient-controlled analgesia; $P < 0.001$) are reduced in RKT compared to OKT [20]. Although various OKT series show the incidence of surgical site infections to be around 15% [21], stage 2b/3 studies show a 1.6% wound complication rate in a total of 125 patients. The blood loss is also reduced (296.8 ml vs. 151.7 ml; $P < 0.001$), partly due to the smaller incision, and also the effect of pneumoperitoneum in reducing venous blood loss. There is also a reduced risk of vascular complications in RKT, contributing to the reduced blood loss [20]. At a median follow-up of 19.1 months, no cases of vascular complications, transplant renal artery stenosis, or vascular thrombosis were reported.

Lymphocele is a common complication of OKT. The lymphatics along the iliac vessels and the graft itself lead to a constant 2.5% incidence of symptomatic lymphocele and a 20% incidence of ultrasound-detected lymphocele [22] in OKT studies. Stage 2b/3 studies of RKT show no lymphocele so far. Ureteric complications have been reported in 1–3% of OKT series [23]. A single case required a redo ureterovesicostomy after three months in our experience of 125 RKTs.

## Modifications of RKT

### Gasless robot-assisted retroperitoneal transplant

A gasless extraperitoneal approach for renal transplant has recently been reported by Tsai et al. from Taiwan [24]. This is a hybrid procedure, having steps of both open and robotic surgery. This technique has the potential advantages of the avoidance of pneumoperitoneum, and a smaller (7–9 cm), muscle-sparing Gibson incision. In case of conversion, the same incision can be extended for open surgery. The ureterovesical anastomosis is performed in an open fashion. Average anastomosis and operation time have been reported as 67.4 ± 22.3 minutes and 257.8 ± 52.7 minutes, respectively, and the average ischemia time was 283.3 ± 51.9 minutes. The mean creatinine at discharge in this series was 1.31 ± 0.31 mg/dl.

This technique is limited by the increasing difficulty in morbidly obese patients, limited working space, and, because it is extraperitoneal the theoretical risk of lymphocele remains as in OKT.

### Robotic transplant with vaginal insertion of graft

Both donor and recipient surgery was performed by Doumerc et al. via transvaginal access using an Alexis® (Applied Medical) retractor [25]. This method may be especially useful in multipara women. Only one case has been published so far, and a prospective study is currently underway to evaluate this technique.

## Current status and conclusions

The above results show that as it currently stands, RKT is a safe alternative to OKT with reduced postoperative pain, reduced analgesic requirements, similar graft function outcomes, and better cosmesis when compared to OKT. RKT is especially beneficial in obese patients. Even though the higher cost of surgery remains a concern, RKT has been adopted at multiple institutions around the world in recent years.

# Minimally Invasive Surgery for Benign Prostate Disease: Laparoscopic and Robotic Techniques

*Mark Ferretti, Amul Bhalodi, & John Phillips*

*New York Medical College, Department of Urology, Valhalla, NY, USA*

## Introduction

Benign prostatic hyperplasia (BPH) is one of the most common diagnoses in a majority of urologic practices. Although the treatment options for symptomatic bladder outlet obstruction have expanded dramatically over the past several decades, the simple prostatectomy remains the gold standard for complicated bladder outlet obstruction associated with a large prostate volume, generally greater than 80 g. Transurethral resection of the prostate (TURP) is a feasible option for the treatment of very large prostates, but this can lead to suboptimal results, and, especially for monopolar TURP, may predispose patients to post-transurethral resection syndrome [1]. It is also known that 12–15.5% of patients receiving TURP required further surgery, while only 1.8–4.5% of those treated with open surgery underwent reoperation within 8 years [2].

Simple prostatectomy is neither simple in technique nor indication and may have short- and long-term complications which are similar to and in some cases more clinically significant than those from radical prostatectomy. Simple prostatectomy is indicated for prostate glands of a volume that may far exceed those of the average prostate gland undergoing prostatectomy for prostate specific antigen (PSA)-identified prostate cancer. Men who undergo simple prostatectomy are on average older and carry more comorbidities than men undergoing radical prostatectomy. The advent of modern medical therapy for prostatic enlargement markedly changed the use of surgery for prostatic hypertrophy, including transurethral and open techniques. When open prostatectomy occurs in today's era, therefore, the patient has often had years of unsuccessful medical therapy, may have endured chronic urinary retention, along with the long-term effects of chronic bladder outlet obstruction. Open surgery in such men was classically associated with blood loss and a transfusion rate exceeding 25%, a prolonged hospital stay, wound healing, and incontinence [3]. Despite the success of the open prostatectomy, there are significant disadvantages, namely the need for an extraperitoneal incision, bleeding requiring transfusion, sphincteric, neurovascular bundle, or rectal injury, prolonged hospital stays, and increased catheterization time [4].

The modern era of minimally invasive surgery for BPH began several years and several hundred cases after the laparoscopic approach to prostate cancer was established. By 2005, groups with experience in robot-assisted laparoscopic prostatectomy (RALP) began adopting the approach to benign prostatic diseases, such as BPH [5]. The technique for BPH using laparoscopy and robotics is different enough from the approach for prostate cancer to warrant this chapter specifically devoted to the development, controversies, and potential future role of minimally invasive surgery in the management of benign prostatic disease.

## Historical context

Open prostatectomy was first performed via cystotomy in 1894 by Eugene Fuller and then popularized by Peter Freyer in 1900 and Robert Proust in the early 1910s. Hugh Hampton Young of Baltimore and Terrence Millin of Dublin, Ireland recognized that cystotomy may add undue morbidity to the procedure and often precluded visualization of the distal adenoma and sphincter [6]. Young proposed a perineal prostatectomy in 1904 to avoid cystotomy. Millin proposed a purely retropubic approach for more control over the prostatic apex during enucleation to avoid traction injury to the urethral sphincter, and more adequate prostatic exposure at the expense of bladder accessibility [2, 7]. The transvesical approach allows the

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.
© 2019 John Wiley & Sons Ltd. Published 2019 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/smith/textbookofendourology

urologist to treat concomitant bladder pathology via direct access to the bladder at the time of adenomectomy and may, therefore, be preferred over the retropubic approach when bladder calculi, large median prostatic lobes, or bladder diverticula are present [8]. Indications for prostatectomy include catheter-dependent urinary retention, bothersome lower urinary tract symptoms that is refractory to medical therapy, frequent urinary tract infections secondary to retention, severe hematuria secondary to prostatic bleeding, bladder calculi, and chronic kidney disease secondary to prostatic enlargement. Open simple prostatectomy may be preferred over TURP with prostates larger than 80 g because TURP was historically associated with morbidity and mortality rates of 55% and 6%, respectively, while the open prostatectomy had mortality rates of 3.3% [8, 9]. Additional indications for open surgery include concomitant surgically amenable bladder conditions, planned concomitant hernia repair, and patients in whom ankylotic or degenerative joint disease of the hip prevents the lithotomy position [2]. Today, mortality rates from both procedures approach 0%, an effect of medical optimization and clearance of most active urinary tract infections prior to elective surgery [2, 8, 10]. Furthermore, modern techniques, such as holmium laser enucleation of the prostate (HoLEP) and potassium titanyl phosphate crystal laser (KTP) have produced favorable results in large prostates and have further decreased the prevalence of open prostatectomy [11–13]. However, drawbacks to laser surgery for prostates >80 g include cost, steep learning curve, specialized equipment, prolonged urethral instrumentation with associated urethral complications (e.g. bladder neck contracture), and the need to morcellate laser-resected tissue free-floating in the bladder. Disadvantages of the open prostatectomy include need for extraperitoneal incision, bleeding requiring transfusion, sphincteric, neurovascular bundle, or rectal injury, prolonged hospital stays, and increased catheterization time [14].

The open surgical approach remained the gold standard for 100 years, the majority of subjects undergoing suprapubic approaches, followed by retropubic, and, least popular, the perineal prostatectomy, first performed by Young in October 1902. A major change came with the advent of laparoscopic radical prostatectomy, first performed by Schuessler in 1991, refined by Bertrand Guillonneau, Guy Vallencien, and Claude Abbou throughout the late 1990s. Mirandolino Mariano is generally regarded as the first surgeon to intentionally course along the retro-adenomatous plane to deliver obstructing adenomas and achieve a pure laparoscopic simple prostatectomy (LSP) of a 173 g prostate [15–17]. Reported advantages over the open approach included improved visualization of the adenoma and venous tamponade due to pneumoperitoneum during dissection and the avoidance of a major lower abdominal incision. Disadvantages were the mechanical challenge in laparoscopic manipulation of very large adenomas, steep learning curve, and complex suturing required in capsule plication and advancement of the bladder neck [4, 18]. Additional disadvantages were the lack of articulation of traditional laparoscopic instruments and the small working space for plicating, anastomotic, and hemostatic suture placement. LSP did, however, improve upon blood loss and length of stay compared to similar series of open prostatectomy and may be performed safely and effectively for the treatment of bladder outlet obstruction secondary to BPH. The advent of robotic surgery has largely supplanted straight laparoscopic techniques for benign disease as robotics has done for radical surgery as well [19].

The first radical robotic prostatectomy was performed by Binder et al. in Hanover in a collaborative effort that pioneered the use of the da Vinci® platform in 2000. This revolutionized an approach that is now performed three times more commonly than open surgery for prostatic cancer. Robotic prostatectomy greatly alleviated the burdens of laparoscopic techniques for cancer surgery and made the procedure more accessible. As applicability of robotics to cancer surgery grew, robotics was also considered for benign surgery. Sotelo et al. are regarded as the first group to have performed a simple prostatectomy robotically in 2008, after years of laparoscopic experience [5]. Robotic surgery offers the theoretical advantage over laparoscopy of a faster learning curve, especially regarding suture techniques, with the presumably shared benefits of laparoscopy, including less perioperative morbidity, improved visibility and precision, faster recovery, and ability to demonstrate technique and disseminate skills via the sharing of surgical videos on the internet and social media platforms. Disadvantages of the robotic approach include cost of the device, longer operative times, incomplete resections, and, when performed, the transperitoneal invasiveness of procedure [20].

## Technique

The technique of straight laparoscopic versus robotic simple prostatectomy is essentially the same, although there are minor differences in port placement, modifications that have occurred in the robotic era, and specific characteristics of robotics owing to its instrumentation. These are described in the text below.

### Port placement

Traditional multiple- and single-access laparoscopic techniques must all ensure an angle and depth of visualization and access to the surgical target, including the distal adenoma and pelvic floor. There are essentially no significant differences, therefore, in port placement for simple or radical laparoscopic prostatectomy. Traditional multiport access prostatectomy begins with placement of five trocars either extra- or transperitoneally [16, 21].

### The extraperitoneal approach

The extraperitoneal (EP) approach involves making a 12 mm infra-umbilical incision and dissecting down to the anterior rectus fascia. This fascia is incised transversely and the bellies of the recti abdomini are separated bluntly in the midline. Finger dissection inferiorly is carried out in the preperitoneal space, taking care to avoid incidental peritoneotomy by applying anterior pressure inferiorly when the posterior rectus fascia disappears below the arcuate line. A 12 mm balloon dissector with 10 mm visual optical channel is inserted and directed inferiorly toward the pubis and into the developed preperitoneal space. The balloon is slowly inflated under direct visualization. In the correct plane, the inferior epigastric vessels remain visible ventrally. The balloon is deflated and the balloon trocar is inserted, a 0° optical lens is inserted, and the space is filled with 10–15 mmHg of $CO_2$. Four additional trocars are inserted under direct vision with two 5 mm trocars close to the anterior superior iliac spines and two 10 mm trocars lateral to the rectus and 5–10 cm below the umbilicus. The proper space during development appears similar to that encountered in typical transperitoneal access. Joseph found that additional advantages of an extraperitoneal approach was the compartmentalization of any urinoma or hematoma, decreased rates of nonobstructive ileus, and decreased rates of early narcotic-dependent pain scores in those with ASA scores of 1–3 [22, 23].

### The transperitoneal approach

The transperitoneal (TP) approach enters the abdominal cavity directly via a midline or transverse supra-umbilical 10 mm incision. The rectus fascia is thinned with dissection using a Crile. A Veress needle is used to insufflate the abdomen through the fasciotomy and after pressures have reached 10 mmHg, the Veress is replaced with a 12 mm camera port. Visual inspection identifies the urachus and the medial umbilical ligaments, the pulsation of the iliac vessels and bladder in the midline. Placement of robotic ports occurs one handbreadth or 5–7 cm from the camera port in a line slightly inferior to a transverse perpendicular. Assistant 5 and 10 mm ports are placed in the right upper and right lower quadrant, respectively. Single-access devices allow for a camera port and two manipulator arm ports, typically through a midline para-umbilical incision but lateral 5 and 10 mm ports will be required for suction and assistant introduction of needle suture material during the case [24, 25].

## Planes of dissection

After successful insufflation of the space of Retzius in an EP approach, or release of the prevesical peritoneum in a TP approach, the arachnoid fibers and areolar tissue of the space are divided to identify the pubic rami. The endopelvic fascia is not punctured and the puboprostatic ligaments are not divided. Apparent in simple prostatectomy is the space in the deep pelvis occupied by the often markedly enlarged prostate not typically encountered in radical prostatectomy. Glands of >300 g may make even dissection to the symphysis pubis challenging and can be deferred. Manual inspection of the transition point between bladder and prostate is replaced by visual landmarks. Deformation of the "shoulders" of the prostate can be appreciated, but may be challenging with large prostates and without interrupting the fibers of the endopelvic fascia. Instead, careful manipulation of the bladder, filled with 200 ml NaCl, may be required to identify the transition to firm prostatic median and lateral lobes from the softer bladder wall. A Foley catheter, when withdrawn to the bladder neck, may not be visible owing to lateral deflection by the obstructing lobes. There is some variation as to the position of the cystotomy. Ideally, the camera will provide a view that is parallel with the planes of dissection and in larger prostates this may require a cystostomy far more cephalad than typically performed for radical prostatectomy.

Leslie et al. employed a "transvesical" approach in which a midline cystotomy is made at the dome of the bladder without development of the space of Retzius at all [26]. Alternatively, an appropriate transverse cystotomy is made that is large enough to expose the adenoma and preferably the ureteral orifices. The prostate must be elevated anteriorly away from the bladder neck and a large adenoma will be difficult to secure with ProGrasp® instruments alone. Instead, a CT-1 suture is often required through an untied figure of eight, secured with a large Weck clip which is then easier to manipulate with the #4 arm ProGrasp. It is not uncommon for the surgeon to make a cystotomy and be unable to identify the cephalad extent of markedly large median lobes with an intravesical component. The CT-1 suture technique will be helpful to bring the lobe up into cystotomy wound to better appreciate its extent.

Identification of the ureteral orifices (UOs) is critical but the use of methylene blue or indigo carmine is largely deferred owing to the obfuscation of landmarks by excreted dye. The operator needs to recall that it is not the prostate which one sees upon inspecting the deformed bladder neck but rather the mucosa and the muscularis of the bladder which are being elevated upwards by the hypertrophic adenomata deep to these tissues.

The critical incision is transverse and inferior to the UOs, allowing for enough remaining bladder neck tissue to be preserved for the plication step later in the case. Robotic "prostatectomists" see little difference between the initial transverse incision of a radical versus a simple case: the difference is what follows. Deep to the mucosa lie the fibers of the detrusor muscle and the soft tissue making up the posterior detrusor apron (PDA). Deep to the PDA lies Denonvilliers' fascia. In a radical prostatectomy, Denonvilliers' fascia is entered to identify and secure the structures of the ampulla, the vasa deferentia, and the seminal vesicles. In a simple prostatectomy, the fascia is not violated. The adenoma is anterior to the fascia and the surrounding prostatic capsule. A dissection too shallow in a radical prostatectomy may identify the potential plane between the true capsule and the adenoma. Similarly, a dissection too posterior (i.e. too deep) in a simple prostatectomy may enter Denonvilliers' fascia and bring into view the vasa deferentia. In the latter case, the operator needs to "course correct" without having to repair or reapproximate the bladder neck and PDA to the prostatic capsule but may need to do so later in the case. Transrectal ultrasound is generally not helpful in directing the operator into the correct plane posterior to the adenoma. In general, the operator proceeds parallel to the rectum once the bladder mucosa has been transversely divided. Anterior and upward traction by the fourth arm (and the retraction stitch secured by the arm or an assistant) will help tease or lead the surgeon into the correct plane posteriorly.

The operator will need to complete the transverse posterior dissection with a circumferential incision around the entirety of the lobes as they elevate the bladder neck. Bleeding in this region is often venous and may be difficult to prevent even with careful bipolar current and thermal energy because their lumens are held patent by surrounding fascial tissue. Once the posterior plane has been developed, the operator moves lateral to develop the similar planes of the lateral lobes. Robotically, or laparoscopically, the maneuver may be difficult as the lobes often occupy a large volume of the operative field. In an open case, the entirety of the prostatic adenomata may be removed en masse. In a laparoscopic case, each lobe may need to be removed separately, thus creating more working space for the subsequent lobes.

The anterior plane is then approached by incision across the 12 o'clock position following the dissection caudally. The operator should now consider that the dissection is to proceed toward the apex, slowly converging so that the posterior and anterior planes meet at the apical urethra. Capsule should surround the lateral aspects of the dissection at all points. For particularly large midline adenomas, the operator may perform a midline capsulotomy inferiorly from the bladder neck caudally. Bleeding through capsular venous branches would not be uncommon here and can be addressed or prevented by the placement of capsular plication sutures using 2-0 Vicryl on an CT-1 needle anteriorly. Care must be taken to avoid deep needle penetration which could enter the adenoma deep to it and prevent development of the dissection plane. Once the urethra is encountered distally, sharp dissection is performed across the urethra to encounter the Foley, which is withdrawn. The adenoma is resected free and placed into a specimen bag.

The operator should be able to appreciate the wide open bladder neck, a large space within the prostatic capsule, and the severed urethral tip in the deep pelvis. Unlike a radical prostatectomy, the preserved pelvic floor often prevents caudal retraction of the severed urethral margin and posterior plication or urethral withdrawal maneuvers are seldom necessary as one would consider prior to a Rocco maneuver. The next 30 minutes of surgical effort often predict the next week of clinical results. Although the field may not be dry, arterial bleeding is rare as the severed branches of the perforating capsular artery (a branch of the inferior vesicle artery) are generally in vasospasm at this point. Venous bleeding is often minimized by retraction of the PDA, the capsule, and the pneumoperitoneum. However, postoperative bleeding will be troublesome, problematic, and almost always clinically relevant, on a critical level, unless prophylactic hemostatic maneuvers are at this point performed. Such maneuvers, described below, will not only help minimize postoperative bleeding but also stabilize the bladder neck and posterior plate to facilitate neo-epithelialization of the created space.

## Retropubic approach

The limits of caudal dissection are the apex of the adenoma, which may be difficult to identify transvesically with large adenomata. An alternative approach is via the prostatic capsule itself. Sotelo et al. recommend the transverse incision just proximal to the prostatovesical junction to avoid disruption of the venous plexus along with resection of adenoma as separate lobes for improved visualization. Finger dissection through a modified suprapubic hand port to improve speed of resection and permit timely hemostatic control can be employed, although this becomes less relevant with operator experience. In an open case, a transverse capsulotomy incision is preferred to avoid caudal enlargement into the apical venous plexuses [18, 22]. Clavijo et al. reported their experience with so-called "intrafascial" prostatectomy for benign disease in prostates with an average size of 80 g. Here, a midline capsulotomy is made, resecting the entirety of the prostate with its adenoma while preserving the posterior fascia and structures of the ampulla, the neurovascular bundles, and the endopelvic fascia [27]. The lateral prostatic pedicles and anterior prostatic veins are first ligated with the latter suture serving as a traction suture during mobilization and dissection of the prostate. The endopelvic fascia is incised ventrally, medial to the puboprostatic ligaments, but high along the lateral prostate surface to allow the neurovascular bundles to be released. The incision is taken to the apex of the prostate and the dorsal vein complex is transected and suture ligated. The endopelvic fascia and neurovascular bundle are then peeled off the prostate using sharp dissection in a retrograde fashion. The urethra is transected as far proximally as dissection permits to maximize urethral length. The seminal vesicles are transected at the prostate base and the specimen removed. Remaining seminal vesicles and vas deferens are oversewn and closed. A vesicourethral anastomosis is performed in a manner similar to that of robotic prostatectomy. The residual anterior prostatic fascia is then sutured to the anterior bladder wall.

### Hemostatic maneuvers and bladder plication

Once the adenoma is removed, the pneumoperitoneum permits a clear field to inspect for arterial capsule bleeders, often amenable to fulguration. The temporary packing of the adenoma defect with Surgicel® (as one would with gauze in an open prostatectomy) is, in this case, logistically not feasible and may be deferred. Bleeders from the bladder neck are derived from the intravesical pedicle and require V-Loc™ hemostastic ligation or figure-of-eight surgical ligatures with a sliding, resorbable suture, such as a 3-0 Vicryl or Monocryl on an RB1 needle. The arterial bleeders are said to enter lateroposteriorly, best described as "at the 5- and 7-o'clock positions," although the operator is advised to oversew the entirety of the posterior intravesical fibers of the PDA as well. Next, plication of the bladder neck is performed to advance the mucosa of the bladder into the defect and further provide hemostatic force in a so-called "trigonization." Mucosal advancement is limited, however, by the attachment of the bladder neck to the laterally preserved prostatic capsule. Advancement can proceed far enough down the capsule to fix a mucosal flap to the posterior floor without undue tension. Coelho et al. have proposed a formal three-step urethrovesical anastomosis whereby a running van Velthoven anastomosis is created to the posterior urethra and the anterior prostatic capsule is sutured to the corresponding area of the bladder neck [28, 29].

### Closure

After simple prostatectomy and plication is completed, easy passage of a Foley catheter, traditionally a 22 Fr three-way catheter, must be demonstrated. Difficulty in passing a Foley will not improve after surgery. Better plication of the bladder neck or fixation of the posterior urethra to the posterior fascia with interrupted sutures may help. A suprapubic tube may be placed in addition to a transurethral Foley, in which case, both catheters can be smaller (e.g. 18 or 20 Fr), two-way catheters. A Jackson–Pratt or similar closed drain is placed near the anastomosis and emerges from the lateral inferior robotic ports. Extraction of the adenoma is best accomplished via surgical Endo Catch™ bags and removed by extending the midline supra-umbilical port through a transverse incision. Large adenomas may require longer incisions and when placed in the midline increases the risks of hernia. A transverse incision with rectus muscle preservation allowing for a running fascial closure anteriorly with 2-0 or 0-0 Vicryl on a UR-6 needle is better.

## Comparative studies

The literature surrounding minimally invasive simple prostatectomies generally suffers from a lack of long-term comparisons and "performance bias," in which the experience levels of the surgeons with their procedures are often not matched and controlled for. However, several attempts have been made in the literature to compare the minimally invasive techniques of robot-assisted simple prostatectomy (RASP) and LSP among each other and against open procedures. The results of such studies are outlined in Table 110.1 [24, 25, 30–33].

In general, open simple prostatectomy (OSP) has been associated with shorter operating room times. No significant difference in incidence or severity of complications or perioperative functional results have been noted. RASP and LSP are associated with shorter catheter duration, shorter bladder irrigation, and shorter hospital stay. In general, estimated blood loss (EBL) is similar between cohorts comparing OSP versus minimally invasive simple prostatectomy. Lucca et al. reported statistically significant lower EBLs in a minimally invasive simple prostatectomy group versus OSP group. Pavan et al. compared EBL among patients undergoing LSP (300 ml) versus OSP (250 ml). In the only study to date comparing LSP versus RASP, Pavan et al. found that both LSP and RASP offer similar operating room times, similar EBLs, and similar rates of major complications [32, 33].

**Table 110.1** Minimally invasive comparative studies.

| Author | Comparison | *N* | Method | Findings | Hospital stay | Foley time | Operative time | EBL |
|---|---|---|---|---|---|---|---|---|
| Baumert et al. (2006) [4] | Open vs. lap | 60 | Retrospective (30 lap vs. 30 open) for prostates >80 g | No significant difference in incidence or severity of complications or perioperative functional results | 5.1 (lap) vs. 8 (open) | 4 (lap) vs. 6.8 (open) | 115 min (lap) vs. 54 min (open) | 367 (lap) vs. 643 (open) |
| Porpiglia et al. (2006) [30] | Open vs. lap | 40 | Prospective RCT (20 vs. 20) | EP LSP provides results comparative to open, with the advantage of significantly lower blood loss | No difference (7.8 days lap vs. 7 days open) | No difference (6.3 days lap vs. 5.6 days open) | No difference (107 min lap vs. 95 min open) | 411 (lap) vs. 687 (open) ($P = 0.004$) |
| McCullough et al. (2009) [25] | Open vs. lap | 280 | Retrospective (96 lap vs. 184 open) | LSP associated with a longer operative time, shorter catheter duration, and shorter hospital stay. No difference in EBL between the cohorts | 6.3 (lap) vs. 7.7 (open) days ($P < 0.0001$) | 5.2 (lap) vs. 6.4 (open) days. ($P < 0.001$) | 95 min lap vs. 55 min open ($P < 0.0001$) | Similar EBL. Hemorrhage rates of 28% vs. 29% reported |
| Parsons et al. (2015) [31] | Open vs. MISP | 6220 | 6027 (OSP) vs. 193 (MISP) | Overall MISP and OSP showed no significant differences | No difference | Not reported | No difference | Not reported |
| Lucca et al. (2015) [32] | Open vs. MISP | 764 | Meta-analysis (27 studies with 764 total MISP) | MISP offers similar improvement in $Q_{max}$ and IPSS as OSP. Although it takes longer, it results in less blood loss and shorter hospital stay | WMD −1.6 days, $P = 0.02$ in favor of MISP | WMD −1.3 days, $P = 0.04$ in favor of MISP | WMD 37.8 min, $P < 0.0001$ in favor of open | WMD −187 ml, $P = 0.015$ in favor of MISP |
| Pavan et al. (2016) [33] | LSP vs. RASP | 319 | Retrospective review (189 lap paired to 130 robot) | Both LSP and RASP offer similar operative time, similar EBL, as well as similar rates of major complications. Age and BMI were found to be predictive of "trifecta" of surgery. "Trifecta" = combination of IPSS score <8, $Q_{max}$ >15 ml/s, and no perioperative complications | No difference (5 days vs. 5 days) | No difference (5 days vs. 5 days) | Similar OR time (120 min for LSP and 150 min for RASP) | Similar EBL (300 ml for LSP and 250 ml for RASP) |

LSP, laparoscopic simple prostatectomy; lap, laparoscopic; RASP, robot-assisted simple prostatectomy; MISP, minimally invasive simple prostatectomy; RCT, randomized controlled trial; OSP, open simple prostatectomy; EP, extraperitoneal; $Q_{max}$, maximal flow rate; IPSS, International Prostate Symptom Score; EBL, estimated blood loss; BMI, body mass index; WMD, weight mean difference.

## Expected complications and preventative measures

Patients who require simple prostatectomy are often older, heavier, and have more comorbidities than men undergoing radical prostatectomy who, presumably, do so because they have a >10 year life span. Medical evaluation for simple prostatectomy, therefore, may require a more extensive workup to identify any occult cardiac, pulmonary, or vascular disease that could complicate the intra- and perioperative course. Steep Trendelenburg positioning is generally tolerated by most men undergoing radical prostatectomy, whereas the older, more ill male undergoing simple prostatectomy may not tolerate Trendelenburg. Importantly, patients undergoing surgical planning for BPH should be screened for prostate cancer as rates of incidental prostate cancer can be found in 6–10% of specimens in larger series and may influence and in some cases limit postoperative therapeutic options [34–46]. Postoperative hemorrhage after open prostatectomy is generally ascribed to bleeding from the bladder neck. With its improved visualization, surgical ligation of suspected bleeders with robotic techniques may be more effective than through open approaches, but postoperative bleeding after robotic surgery is still prevalent (Table 110.2). Most report a minimal requirement of continuous bladder irrigation after robotic simple prostatectomy but one must be prepared for traditional maneuvers should gross hematuria become problematic. A secure posterior bladder neck plication, therefore, is critical to facilitate the easy passage of a Foley catheter into the bladder itself without undermining a poorly repaired PDA.

## Conclusions

Simple prostatectomy is a safe, effective, and well-tolerated procedure for the treatment of BPH and may be performed via several approaches. In the new era of healthcare, costs are becoming an increasingly important part of decision-making. The costs of investing in new technology or traveling to distant centers must be weighed against perceived and real benefits among the various technologies. Robotic simple prostatectomy offers the advantage of decreasing hospital stay and catheter time while providing outcomes consistent with those demonstrated by OSP of improved lower urinary tract symptoms and adequate bladder emptying.

See accompanying Video 110.1.

**Table 110.2** Hemostatic maneuvers.

| Author | Approach | Maneuver |
|---|---|---|
| Presman and Rolnick (1949) [47] | Transvesical | Pack the prostatic fossa with gauze for 5 min or more after prostate enucleation |
| O'Conor(1970) [48],<br>Magri (1975) [49] | Transvesical | Direct suture of bleeding vessels in prostatic bed, vesicourethroplasy with full-thickness bladder wall flaps to cover the denuded prostate |
| Hryntschak (Beck et al. 1970) [50],<br>Witherington (1974) [51] | Transvesical | Plication of the prostatic fossa: 2 separate 1-0 chromic sutures on GU needle used in running fashion from adjacent to bladder neck to the distal prostate just above verumontanum. Tie together in middle |
| Shaikh and Malement (1971) [52] | Transvesical | Bladder neck partition sutures: 1-0 Nylon pursestring suture around bladder neck starting from posterior margin of bladder neck (mucosa and muscle) and carried anteriorly to the midline where they exit through the entire thickness of bladder. Catheter placed in bladder and bladder closed carefully without involving pursestring sutures. Partition sutures brought out through abdominal wall. Tie around a gauze pad on abdominal wall. May remove on first postoperative day |
| Walsh and Oesterling (1990) [41] | Retropubic | Suture dorsal vein complex distally with a mass clamp ligature. Incise the puboprostatic ligaments and suture lateral pedicles at the bladder neck |
| Gregoir (1969) [53] | Retropubic | Place a suture at the distal prostatic apex through the adenoma to control all deep dorsal vein bleeding as well as ascending branches of the dorsal penile artery |
| Amen-Palma and Artega (2001) [54] | Retropubic | Place lateral pedicle and dorsal vein complex sutures only after prostate enucleation |

## Development, indication, and anatomy of laparoscopic adrenalectomy

### Development of laparoscopic adrenalectomy and its efficacy

The adrenal grands are located deep in the trunk of the body. Therefore, large abdominal incisions are necessary to approach the adrenal by open surgery. Following the development of laparoscopic nephrectomy in 1990, several urologists and endocrine surgeons conceived of the idea of laparoscopic adrenalectomy (LA). The first LA was performed by Go et al. on January 17, 1992 in Japan [1], and the first publication was by Higashihara et al. in July, 1992 [2], followed by Gagner et al. in November, 1992 [3], who performed their first case in March, 1992. After these pioneers developed the technique independently, LA was became widespread as one of the most efficient laparoscopic surgeries [4, 5]. The small size of the majority of adrenal tumors accounts for the usefulness of the laparoscopic approach.

Nowadays, almost all clinical guidelines strongly recommend laparoscopic surgery as the gold standard approach for small benign adrenal tumors, including pheochromocytomas, if the tumor has not invaded the surrounding tissues [6–8]. Even though there is no high-level supportive evidence such as prospective randomized studies comparing laparoscopic and open adrenalectomies, it is generally believed that LA is associated with less postoperative pain, shorter hospital stay, earlier recovery, and similar long-term outcomes compared with open surgery [6–8].

### Indications for laparoscopic adrenalectomy

Indications for laparoscopic surgery for adrenal tumors vary depending on the surgeon's experience. In particular, large tumors, malignant tumors, and pheochromocytomas make laparoscopy more challenging. According to the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) guidelines, a tumor size ≥7.5 cm has been shown to be an independent risk factor for longer operating times, more blood loss, longer hospital stay, and a higher conversion rate to open surgery [6]. With regard to malignant tumors, the European Society for Medical Oncology (ESMO) clinical practice guidelines for adrenal cancer recommend LA as a safe and effective procedure for pheochromocytoma and for a select group of patients with small adrenocortical cancers (ACCs) (<8 cm) without preoperative evidence of invasiveness [9]. Metastatic adrenal tumors are also candidates for laparoscopic surgery when not invaded and not too large. A matched controlled study demonstrated similar clinical outcomes including capsular injury rate and cancer-specific survival with a median follow-up of 39.3 months for laparoscopic and open adrenalectomy for metastatectomies or ACC less than 10 cm diameter [10]. Most importantly, standard principles of oncologic surgical treatment should be strictly respected [9], and open conversion is warranted when difficult dissection is encountered due to tumor adhesion or invasion or when enlarged lymph nodes are seen. The Endocrine Society clinical practice guidelines for pheochromocytoma and paraganglioma recommend LA for most adrenal pheochromocytomas, but recommend open resection for tumors larger than 6 cm or for invasive pheochromocytomas [11]. It is recommended that paragangliomas be resected by open surgery because of the high incidence

of malignancy, but laparoscopic resection can be performed for small, noninvasive paragangliomas in surgically favorable locations [11]. Again, the surgical indication depends on the surgeon's experience and the characteristics of the tumor.

The indications for surgical dissection of incidentally identified nonfunctioning adrenal tumors depends on the size of the tumor, increase in its size during follow-up, and the radiological findings. The Canadian Urological Association's guidelines recommend considering surgical excision for tumors more than 4 cm in diameter; this size has been shown to provide the best sensitivity (93%) in predicting malignant processes [7]. However, this marker has low specificity (42%) due to the low prevalence of ACC [7].

### Perioperative care

A full endocrine workup is mandatory for all adrenal tumors before surgery, even when there is apparent hormonal activity such as in patients with Cushing syndrome or pheochromocytoma. Some tumors simultaneously excrete more than one hormone, such as catecholamine plus cortisol or aldosterone plus cortisol. In these cases, appropriate perioperative management is required to prevent postoperative adrenal insufficiency [12]. In the case of a pheochromocytoma, preoperative treatment with alpha blocker administration for at least 7–14 days, a high-sodium diet, and fluid intake are required to normalize hypertension and to reverse catecholamine-induced blood volume contraction [11]. These management techniques are important to prevent severe hypotension after tumor removal.

Postoperatively, intensive monitoring is mandatory for pheochromocytoma cases to prevent hypotension and hypoglycemia. For cortisol-producing tumors, appropriate cortisol supplementation is required with close follow-up by endocrinologists.

### Vascular anatomy of the adrenals

Understanding the vascular anatomy of the adrenal is important for conducting safe LA, especially for large or highly vascularized tumors such as pheochromocytomas (Figure 111.1). Arterial supply to the adrenal comes from the aorta (the middle adrenal arteries), the renal artery (the inferior adrenal artery), and the inferior phrenic artery (the superior adrenal artery) [13]. All adrenal arteries are small in diameter and can be severed with sealing devices or ultrasonic scalpels without clips.

The left main adrenal vein comes from the anterior surface of the left adrenal, and inflows into the left renal vein. A communicating branch between the left inferior phrenic vein and the left adrenal vein is present in 34% of people according to a cadaveric study [14]. The left superior adrenal veins run into the left inferior phrenic vein, and the inferior left adrenal vein, which has a small diameter, runs into the renal vein just distal to the left adrenal vein. The right adrenal vein is very short, comes from the junction of the hepatic area and the area related to the inferior vena cava, and inflows into the posterolateral aspect of the vena cava. The right superior adrenal veins run into the right inferior phrenic vein, and the right inferior adrenal vein runs into the right renal vein. Several small veins from the adrenal run into the right renal capsular veins in both sides. A retrospective study of LA showed that a significant number of patients (13%) had variant venous anatomy such as no main adrenal vein, two adrenal veins, or drainage to the hepatic vein [15]. Because of the variations in venous anatomy, severing the adrenal vein does not result in the occlusion of all adrenal venous returns in a majority of patients. However, in the case of large tumors having a large blood supply, occlusion of the adrenal vein, the main venous return, may result in congestion of the adrenal and bleeding from the tumor surface. It is recommended that the main adrenal vein be occluded using clips, although it can be severed using electrosealing devices.

## Approaches to the adrenal and complications of laparoscopic adrenalectomy

### Laparoscopic approaches to the adrenal

LA was first developed using a transperitoneal approach [1–3], and the use of a retroperitoneal approach started later. There are anterior and lateral variants of the transperitoneal approach, and lateral and posterior variants of the retroperitoneal approach (Figure 111.2). The retroperitoneal approach was first reported in 1994 using the lateral approach in the lateral decubitus position [16]. The posterior retroperitoneal approach was first performed in 1994 [17]. It is performed with the patient prone, and is suitable for bilateral diseases. For large tumors, transperitoneal lateral approaches are the most widely used, whereas small tumors less than 5 cm in diameter are treated with various approaches. The transperitoneal anterior approach, where the spleen is not moved medially, is seldom used now for the left adrenals; however, it is still used for small right adrenal masses where the liver is not moved.

Comparing transperitoneal and retroperitoneal LA in a case–control study, longer operative duration and fewer perioperative complications were reported in retroperitoneal LA [18]. However, no differences between the two approaches were found in another study [19].

**Figure 111.2** Laparoscopic approaches to the adrenal.

Two prospective randomized studies compared transperitoneal LA and lateral retroperitoneal LA [20, 21]. Both demonstrated similar operative times, estimated blood loss, postoperative analgesic use, hospital stay, and complication rates; however, convalescence was shorter with the retroperitoneal approach than the transperitoneal approach, probably due to less peritoneal irritability postoperatively. According to another recent randomized controlled trial comparing posterior retroperitoneal LA and transperitoneal LA, retroperitoneal LA is superior in operative duration, bleeding, postoperative pain, recovery from surgery, and postoperative hernia [22]. A recent report noted that outcomes of retroperitoneal LA for obese patients are the same as those of transperitoneal LA [23]. Retroperitoneal LA can be performed for patients with larger adrenal tumors [24].

Compared to the retroperitoneal approaches, the transperitoneal approach makes it easier to understand surgical anatomy and may be suitable for less experienced surgeons. It is recommended that the approach should be selected based on the condition of the patient, the characteristics of tumor and the surgeon's experience [8].

## Complications of laparoscopic adrenalectomy

Incidence of complications and open conversion depends on the indication and the surgeon's experience. It is reported that average blood loss, open conversion rate, and complication rate were 81 ml, 2%, and 8.9%, respectively [5]. Blood transfusions and organ injuries were both less than 5% [5]. Liver injury possibly occurs by retraction or during adrenal dissection on the right side. Hemostasis is usually achieved by coagulation by energy devices and hemostatic sheets. The spleen is so fragile that massive injury sometimes requires splenectomy. Unrecognized injury of the pancreas may result in pancreatitis (pancreatic fistula) in early postoperative days. Pneumothorax by diaphragm injury is recognized as a paradoxical movement of diaphragm. Sutured closure is required.

## Special concerns in laparoscopic adrenalectomy

Avoiding capsular injury during adrenal surgery is very important for all adrenal surgeries. This is especially true for cortical cancers, metastatic tumors, and pheochromocytomas that have more than a 10% incidence of malignancy. Even if preoperative diagnosis is adrenocortical adenoma, some could be ACCs, especially when the tumor is more than 4 cm in diameter. Only aldosterone-producing adenomas (APAs) have a very low incidence of malignancy. The incidence of capsular injury is relatively common during laparoscopic adrenalectomies [25], and local recurrences of pheochromocytoma after laparoscopic surgery are reported in the literature [26].

## Partial adrenalectomy

It is generally accepted that unilateral total adrenalectomy is the standard for adrenal tumors when the patient has a normal contralateral adrenal gland. Some authors have recommended partial adrenalectomy for unilateral APAs to achieve better adrenal function postoperatively [27]. However, it is reported that 27% of APAs have multiple microadenomas in the adrenal and 2 of 29 cases had persistent aldosterone production after partial adrenalectomy [28]. For bilateral tumors such as pheochromocytomas in multiple endocrine neoplasia type 2 (MEN2) cases, tumors arising after contralateral adrenalectomy, or hereditary pheochromocytomas, partial adrenalectomy is a treatment option. It was reported that Addisonian crisis occurred in 35% of cases and the mortality rate was 3% after bilateral adrenalectomies [29]. To prevent permanent postoperative cortisol substitution while preserving sufficient adrenal function, at least a third of the unilateral adrenal tissue should be preserved [30]. Because the incidence of malignant pheochromocytoma is less than 5% in MEN2 patients, less than 10% in von Hippel Lindau disease (VHL) patients, and 34–70% in succinate dehydrogenase B (SDHB) mutation patients, MEN2 and VHL are good candidates for partial adrenalectomy for pheochromocytoma [30]. The recurrence rate of pheochromocytoma in MEN2 patients after partial adrenalectomy in the ipsilateral adrenal was reported to be 3% (4/153 adrenals) after a median follow-up period of 10 years [30].

To preserve adrenal function in partial adrenalectomy, it is important to keep vascular supply to the residual adrenal tissue. Separation of the adrenal from the surrounding tissue should be minimized to preserve arterial supply and venous return. Keeping the main adrenal vein intact is not required to preserve adrenal function in partial adrenalectomy [31]. To control bleeding from the cut surface of the adrenal gland, bipolar or soft coagulation with or without hemostatic agents is effective in a majority of cases.

## Surgical techniques for laparoscopic adrenalectomy: transperitoneal approach

### Equipment

The instruments used in LA are highly dependent upon the surgeon's preference, surgeon's surgical style, or institutional equipment available.

- *Basic set*: These instruments may include: ports, graspers (e.g. Maryland type), right-angle dissector, scissors, monopolar generator, bipolar generator, suction–irrigation, liver retractor, hemoclips, gauze for laparoscopy.
- *Optional*: Sealing device, ultrasound scalpel, Veress needle, vascular-load endoscopic stapling device, and other instruments.

### Patient positioning

The patient is placed in the right or left kidney position (i.e. left or right lateral decubitus position, respectively). The authors prefer that the patient is rotated approximately 70–80° for the anterior approach, and full lateral decubitus position for the lateral approach. All pressure points should be padded to prevent nerve compression injuries. The surgeon, laparoscopist, and assistant usually stand on the patient's abdominal side. In right-sided adrenalectomy, the assistant is usually required to retract the liver.

### Right side

#### Anatomic considerations

The anatomy around the adrenal gland differs slightly between the right and left sides, and the surgical approach should be chosen with consideration of these differences. On the right side, the adrenal gland is located next to the inferior vena cava (IVC). After kidney position is taken, the duodenum moves medially. The anatomically important points to consider is the relationship between the adrenal gland and IVC or liver. The medial side of the adrenal gland is sometimes hidden behind the IVC. The upper side of the adrenal gland is placed behind the liver and, importantly, the upper part of the normal adrenal gland is sometimes physiologically fused with the normal liver tissue without a distinct border (adrenohepatic fusion) [32, 33].

#### Surgical technique

##### *Port position*

Port position is a very important issue in laparoscopic surgery, but it depends on the body shape of the patient and the surgeon's preference. The author places four ports during transperitoneal right-sided adrenalectomy: a 12 mm camera port, a 10 mm port for the right hand, a 5 mm port for the left hand, and a 3–5 mm port for liver retraction (Figure 111.3). The first port is placed by the Veress needle technique or open Hasson technique. The author prefers the open technique, in which the first port is placed slightly lateral to the midclavicular line and two fingerwidths away from the costal edge. Surgeons should be aware that the body surface landmarks (e.g. the umbilicus) are usually shifted to the

△ : Liver retractor (5 mm), dotted line : midclavicular line

**Figure 111.3** Port position for transperitoneal right laparoscopic adrenalectomy.

left side in the right kidney position. The precise positions of the other ports are determined after the insufflation. The right- and left-hand working ports are usually placed parallel to and two fingerwidths from the costal edge. The left-hand port (5 mm) is placed four fingerwidths (6–8 cm) caudolaterally from the camera port, and the right-hand port (10 mm) is placed four fingerwidths (6–8 cm) medial-cephalad from the camera port. The port for the liver retraction (5 mm) is placed near the xiphoid process after confirming the liver size and falciform ligament. The ports are placed relatively lateral in the lateral approach compared to the anterior approach.

***Liver retraction and peritoneal incision***

The surgeons should first observe the surgical field in the upper abdominal quadrant. In some cases, the intestine is adhered to the abdominal wall or the peritoneum is adhered to the posterior surface of the liver. If the lateral side of the liver is attached to the diaphragm, a peritoneal incision is required to safely retract the liver in the medial-cephalad direction. After retracting the liver, the IVC may serve as a good landmark. Even in patients with a large amount of fatty tissue, the IVC may be recognized at the inferior edge of the liver. The peritoneum is incised at the lateral edge of the IVC from the upper edge of the right renal vein to the inferior edge of the liver (Figure 111.4, line b). The surgeon should take care to prevent duodenal injuries. The peritoneal incision is extended laterally along the inferior edge of the liver (Figure 111.4, line a). This incision may be done earlier, when retracting the liver.

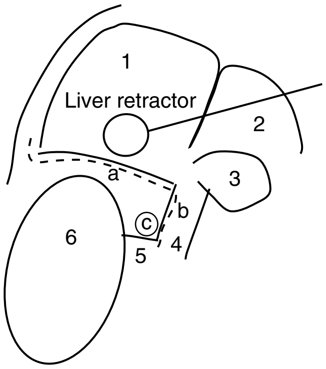

**Figure 111.4** Peritoneal incision in the transperitoneal anterior laparoscopic adrenalectomy. 1, Right lobe of liver; 2, left lobe of liver; 3, gall bladder; 4, inferior vena cava; 5, right renal vein; 6, kidney. Lines a and b, and circle c are explained in the text.

***Dissection around the adrenal gland***

The dissection is started at the median and inferior borders of the adrenal gland. To prevent injury to the adrenal gland, the dissection should be performed on the right-side surface of the IVC and the right kidney surface, not the surface of the adrenal gland. The author first dissects the fatty tissue in a wide and shallow manner, then more deeply dissects the fatty tissue at the junction of the IVC and renal vein (cephalad edge) to reach the surface of the psoas muscle (Figure 111.4, circle c). Small arteries and veins are located in this region, and the apical branch of the right renal artery is sometimes observed. Once the psoas surface is reached, the adrenal gland is easily elevated anteriorly, and the layer between the adrenal gland and psoas is usually avascular. Dissection between the adrenal gland and kidney is usually easily performed. The dissection between the adrenal gland and IVC progress cephalad, and the adrenal vein is then identified. Importantly, the surgeon should not completely dissect the lateral side (right side) of the adrenal gland before median dissection because the lateral retraction becomes difficult. This facilitates dissection between the IVC and median side of the adrenal gland and dissection and clipping of the adrenal vein, which can be elongated.

After dividing the adrenal vein, dissection progresses to the superior border of the adrenal gland. The adrenal gland and liver are sometimes tightly adhered, and histopathological examination shows intermingling of parenchymal cells (infiltration through the fibrous capsules). When the tumor is attached to the liver, the adrenal gland may be removed with the liver. Extensive coagulation and/or a hemostasis sheet is useful. The lateral side (right side) of the adrenal gland is easily dissected. After the adrenal gland is completely free, it is retrieved with a specimen bag.

## Left side

### Anatomic considerations

The left adrenal gland is located next to the aorta and right renal vein. The pancreas covers the anterior surface of the adrenal gland, and median replacement of the pancreas is mandatory. Other than its association with the pancreas, the left adrenal gland is usually isolated by surrounding fatty tissue.

### Surgical technique

#### *Port position*

The port position is usually the mirror image to that of right-sided adrenalectomy except for the liver retraction port. The authors use three ports: a camera port, right-hand working port (10 mm), and left-hand working port (5 mm).

#### *Mobilization of the spleen and descending colon*

The peritoneal incision is started at the splenic flexure of the colon. It is important to incise the peritoneum close to the colon; if the incision is too lateral, the left kidney moves medially and the dissection around the adrenal gland becomes difficult. The peritoneal incision progresses to the lower pole of the left kidney in the caudal and lateral attachment of the spleen to the cardiac notch of the stomach. Using this incision, the descending colon and spleen are mobilized medially. The spleen is very fragile, and care should be taken during its dissection. Injury to the spleen sometimes necessitates splenectomy.

#### *Dissection around the adrenal gland*

Dissection of the pancreas tail should also be carefully performed to prevent pancreatic injury, which is sometimes hard to recognize. Postoperative pancreatic fistulas may be severe. Dissection is usually performed between the Gerota's fascia and mesocolon. The authors sometimes dissect the pancreas from inside Gerota's fascia. This facilitates dissection of the left renal vein, which is usually recognized by the venous waveform, and the cephalad surface of the left renal vein is dissected. The left adrenal vein is easily identified. The dissection and ligation of the left adrenal vein is easier than that of the right side. After ligation of the left adrenal vein, the fatty tissue between the left renal vein and adrenal gland is dissected until the psoas muscle (or diaphragm) is reached. Upon reaching the psoas surface, the layer between the adrenal gland and psoas is usually avascular, and the adrenal gland is easily elevated anteriorly. The median and lateral sides of the left adrenal gland are dissected in the cephalad direction. The authors prefer to start from the median side. If the lateral attachment is divided, the adrenal gland moves medially and dissection of the medial side becomes difficult. After the adrenal gland is completely free, it is retrieved with a specimen bag.

# Surgical technique for laparoscopic adrenalectomy: retroperitoneal lateral approach

## Approach considerations

The retroperitoneal approach does not require entry into the peritoneal cavity, and thereby avoids potential injury to the intraperitoneal organs. Laparoscopic retroperitoneal adrenalectomy (retroperitoneal LA) can be performed for patients with a history of abdominal surgery. This approach can be indicated for younger patients who may have to undergo abdominal surgery in the future because peritoneal adhesions can be avoided. Retroperitoneal LA is reported to be a safe and feasible procedure for small benign adrenal tumors, as well as paragangliomas, in retrospective cohorts [34, 35]. However, the working space of this approach to manipulate forceps is narrower than that of the transperitoneal approach. For this reason, retroperitoneal LA is reported to be unsuitable for patients with large adrenal tumors. It also takes a longer time to learn this procedure for many inexperienced surgeons.

There are two approaches to retroperitoneal LA: the lateral flank approach and the posterior lumbar approach [16, 17]. In the latter, patients are placed in the prone position, with their head lifted up, allowing direct access to the central adrenal vein before separating the gland from perinephric fat tissue. However, because this approach is only used by experienced surgeons in a few centers, this chapter mainly describes the lateral flank approach.

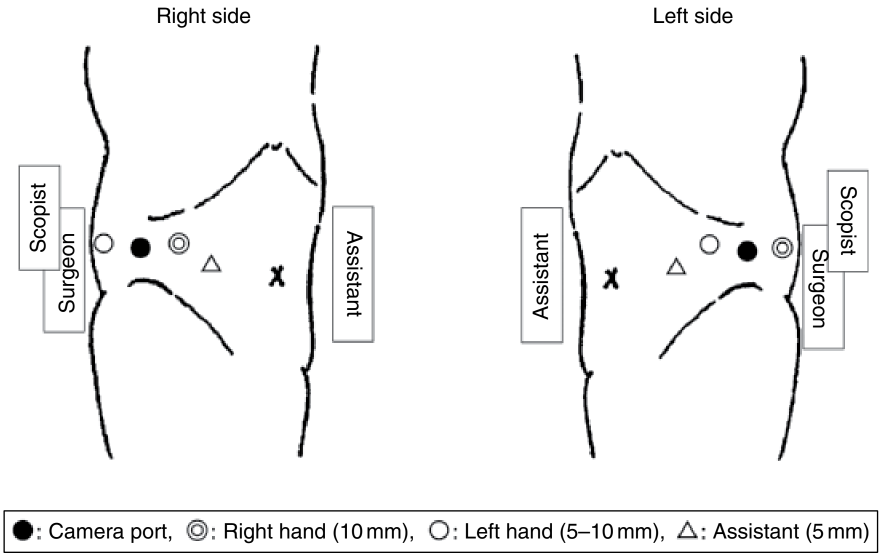
## Patient positioning

In retroperitoneal LA with the lateral approach, the patients are placed in the full lateral decubitus position and secured in the standard manner. As necessary, the jackknife position is useful to extend the distance between trocars to manipulate forceps and scissors in the limited working space. The working space provided by the lateral flank approach is not enough to manipulate a large tumor [3]. The surgeon faces the back of the patient, the scopist stands on the same side, and the assistant stands on the opposite side.

## Surgical technique

### Port position

Port placement for retroperitoneal LA is shown in Figure 111.5. A skin incision (15–20 mm) is made at the midaxillary line above the iliac crest. The external and internal abdominal oblique muscles and the transverse abdominal muscle are expanded using surgical retraction



Right side
Left side

**Figure 111.5** Port sites for the retroperitoneal lateral approach.

hooks. After the incision is deepened to the retroperitoneal space, the posterior perinephric space is developed using gentle digital dissection. The costal and iliac bones can be fingered at this time. To develop adequate working space, a balloon dilator can be used to expand the space outside the posterior lamina of Gerota's fascia. The working space is expanded while observing the retroperitoneal cavity by an endoscope through the balloon. A 10/12 mm trocar for an endoscope port is inserted, and the posterior perinephric space (outside Gerota's fascia) is expanded with $CO_2$ gas insufflation at a pressure of 10 mmHg.

The endoscope is inserted, and the second trocar (10/12 mm) is inserted at the posterior axillary line. The third trocar (10/12 mm, 5 mm is useful for experienced surgeons) is inserted outside the peritoneal reflection at the anterior axillary line under direct endoscopic vision. An additional trocar (5 mm) if needed may be placed above the iliac crest to retract the kidney.

#### Making working space in the retroperitoneal space

After the insertion of all trocars, the insufflation pressure is lowered. In obese patients, the flank pad might be removed out of the body to facilitate intraoperative manipulation. The posterior lamina of Gerota's fascia is incised widely along the attachment of the fascia to the psoas muscle to the origin of the diaphragm and separated from the iliopsoas muscle with careful attention to protection of the peritoneum from injury. The working space is more expanded by this manipulation. Then, further separating Gerota's fascia from the peritoneum allows identification of the conically shaped fat between the peritoneum and the diaphragm. If possible, it is better to separate Gerota's fascia from the peritoneum near the renal hilus. Gerota's fascia is incised, and the perinephric fat is dissected free from the diaphragm and the psoas muscle. After perinephric fat is separated from the peritoneum, the adrenal gland and the kidney become apparent.

#### Dissection around the adrenal gland

Perinephric fat is dissected to separate the adrenal gland from the kidney, and, if necessary, the upper pole of the kidney should be obvious. It is important not to expose the adrenal gland and tumor. The procedure should be to remove a loaf of adipose tissue surrounding the gland. A peritoneal injury would lead to severe difficulty in manipulating forces due to retroperitoneal working space contraction. On this occasion, holding up the peritoneal membrane with forceps through the additional trocar at the subcostal region is needed to expand the working space. Adipose tissue, including the gland, is separated from perinephric fat. If necessary, holding down the upper pole of the kidney with forceps through the additional trocar to the caudal side facilitates adrenalectomy. Small vessels excluding central veins can be ligated using an ultrasonically activated scalpel or a vessel-sealing device.

### Left side

The left renal vein is exposed and the adrenal vein is identified as an ascending branch of the renal vein. After securing the adrenal vein with three clips, the vein can be dissected keeping two clips secured in the central side of the vein. The inferior phrenic vein often communicates with the adrenal vein; ligation of the inferior phrenic vein is needed in such cases. The gland with adipose tissue is separated completely from perinephric fat and is bagged by a specimen retrieval bag through the second trocar.

After repositioning the endoscope through the third trocar, the bag is retrieved through the first trocar with forceps. If the gland and tumor are large, incision of the skin is needed to remove the bag from the body. Again, the endoscope is put through the first trocar to check for hemorrhage. If it is necessary to achieve adequate control of a hemorrhage, bipolar forceps and/or blood derivatives containing fibrin may be applied.

### Right side

Access to the right adrenal vein from the posterior or inferior-caudal side of the gland is feasible to separate the gland from the vena cava. Careful manipulation of the forceps is required because the right adrenal vein is short. When the right adrenal vein has a common vessel with the short hepatic vein, adequate exposure of the adrenal vein is necessary for ligation. After securing the adrenal vein with three clips, the vein can be dissected with two clips secured in the central side of the vein.

If it is not enough to separate the gland from the upper pole of the kidney, there is a risk of injuring the lower pole of the gland. The whole gland with adipose tissue is separated completely from perinephric fat and the subhepatic surface, and then it is bagged with a tissue retrieval bag. When the gland adheres firmly to the subhepatic surface, it will be necessary to resect the hepatic surface to separate the gland. When hemorrhage from the hepatic surface is difficult to control, covering it with a blood derivative containing fibrin can often be helpful.

## Laparoendoscopic single-site adrenalectomy

### History of laparoendoscopic single-site adrenalectomy

Since the first report of LA in 1992 [2, 3], this minimally invasive surgery to resect adrenal lesions has increased and spread widely. LA has been shown to be superior to conventional open adrenalectomy as its safety improved and morbidity decreased. Therefore, LA is now recognized as the gold standard procedure for the surgical resection of most adrenal tumors. Innovative techniques are continuously being developed in medical engineering fields, and new and revolutionary less-invasive surgery has emerged. One of the results is the emergence of laparoendoscopic single-site (LESS) surgery and natural orifice translumenal endoscopic surgery (NOTES) as minimally invasive and maximally effective cosmetic procedures.

Hirano et al. first reported LESS adrenalectomy (LESS-A) in 2005 by a retroperitoneal approach using conventional laparoscopic instruments [36]. Castellucci et al. in 2008 reported a transperitoneal LESS-A procedure using three 5 mm conventional ports [37]. Cindolo et al. then reported the first successful experience of transperitoneal LESS-A using a multichannel single port [38]. Since then, various multichannel single ports have been developed and LESS-A has become widely used [39]. A recent large international series study demonstrated that LESS represents the most commonly adopted technique as well as conventional laparoscopic adrenalectomy (CLA). From 2008 to 2013, LESS-A had the fastest increase in utilization at 6%/year among the techniques. Not surprisingly, LESS-A was used more often for benign indications compared to other adrenal surgeries, suggesting that surgeons approached this novel technique with some caution. Interestingly, institutions from Asia and South America reported high rates of LESS-A [40]. Whether adoption of LESS in these countries is driven by patient demand and a focus on cosmetic outcome is speculative and remains to be determined. Furthermore, safety and efficacy remain the key factors in the decision-making process of patients undergoing minimally invasive surgery [41].

### NOTES or LESS?

CLA requires at least three ports to complete adrenal excision since the surgeon uses two ports, and the scopist uses a port and sometimes a port for retraction when needed. Technical difficulty often increases the number of ports. Although LA is a minimally invasive surgery, a port site may induce pain or muscle spasm, or prolong recovery time, resulting in deteriorated patient quality of life. In order to improve these drawbacks, NOTES was developed. NOTES is based on the concept that the surgeon uses a natural orifice (mouth, anus, or vagina) as an access and approaches the intraperitoneal space through a small incision in the luminal wall. Since there is no wound on the body surface with NOTES, it was expected to be the ultimate minimally invasive surgery. However, NOTES is extremely hard from a technical standpoint and further improvements in the instruments are needed. Whether NOTES will be useful is still unknown. On the other hand, there has been increasing enthusiasm and growing interest in LESS over the last decade since LESS seems to be more reliable than NOTES.

### Techniques and instruments

LESS-A has two access routes: transperitoneal and extraperitoneal. The most common access route for LESS-A has been the umbilicus, for obvious cosmetic benefits. The umbilicus provides a place in which the scar can be partially hidden from view, resulting in improved cosmesis with LESS through the umbilicus.

Nevertheless, transperitoneal LESS-A through the umbilicus is still challenging because the distance from the port to the tissue is longer than in the conventional laparoscopic approach. The approach becomes more tangential in direction in LESS (Figure 111.6). The angle of approach of the instrument feels different compared with conventional laparoscopic surgery, and there is a tendency for the surgeon to grasp the second- or third-best site since it is difficult to approach the target tissue in a straightforward manner. This might contribute to an increase in tissue regrasping due to inadequate or insufficient countertraction. The articulating grasp has insufficient gripping power to allow the surgeon to continue grasping the tissue. Improvement in articulating instruments must be achieved to improve operability.

LESS-A involves a limited surgical space, which often results in the instruments interfering with each other, so-called "sword fighting." To reduce this, bent instruments are required to create a wider working space. A 5 mm flexible laparoscope (Olympus Surgical, Tokyo, Japan) should also be utilized to keep the scope away from the surgeon's instruments [42]. Even though sword fighting is still an obstacle in LESS-A and one-handed manipulation remains prevalent, these obstacles decease as experience increases. To avoid it, surgeons spend a greater proportion of an operation conducting one-handed maneuvers in the early phase after starting to perform LESS [42]. However, the use of one-handed maneuvers increases the pneumoperitoneum time and the risk of tissue damage. Because of this, the "crossover technique" was developed (Figure 111.7), in which the instruments are crossed at the platform (Figure 111.8). Although this can initially be confusing, after the surgeon has mastered the crossover technique, performing it with bent instruments creates an appropriate operative angle and adequate surgical space. Fukumoto et al. reported that it takes 30 cases to master LESS-A [43]. They found that tumor size and visceral fat prolonged pneumoperitoneum time, and patients with large tumors tended to lose more blood. However, the effects of these predictors of worse surgical outcomes were overcome as the surgeon gained experience.

The retroperitoneal approach has some advantages, including more direct access to the retroperitoneal organs, less need for visceral retraction, and elimination of the risk for intraperitoneal contamination with infectious organisms [20]. However, the retroperitoneal space is limited, and articulating and curved instruments are not as useful as they are in the transperitoneal approach. Taken together, the most common transperitoneal LESS

CLA
LESS-A

**Figure 111.6** The distance from the port to the tissue in laparoendoscopic single-site adrenalectomy (LESS-A) is longer than in conventional laparoscopic adrenalectomy (CLA).

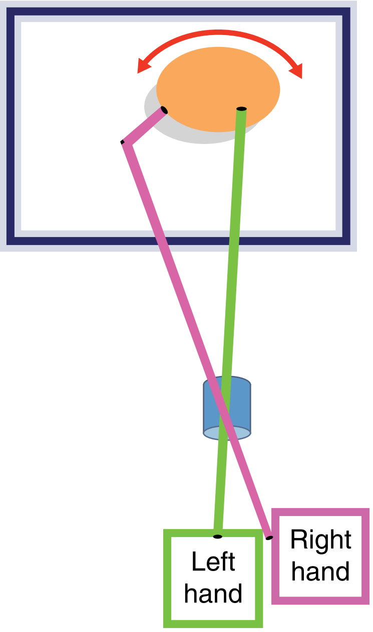

**Figure 111.7** In the crossover technique, the instruments are crossed at the platform and bent instruments create an appropriate operative angle and adequate surgical space.

through the umbilicus has a wider working space, although transperitoneal LESS requires the crossover technique using bent instruments.

## Indications

In general, all patients eligible for CLA can be considered for LESS-A depending on the surgeon's experience and technique. Benign adrenal tumors are a definite indication for CLA. Moreover, it is increasingly used for pheochromocytoma and some malignant cortical tumors preoperatively diagnosed as benign tumors. Nevertheless, Hasegawa et al. reported that factors prolonging pneumoperitoneum time in 50 early cases of LESS-A were patient visceral fat tissue, pheochromocytoma, and tumor diameter (>5 cm) [44]. When introducing LESS-A, patient selection criteria should be stringent. In addition to disease features (locally advanced or invasive), patient characteristics (visceral fat tissue, BMI, and previous surgical history) should be considered. According to these factors, the surgeon should choose relatively easier cases and may expand the indications with increasing experience. However, Fukumoto et al. found that no factor affects operative time as much as a surgeon with a lot of experience performing the crossover technique [43].

On the other hand, what kind of patient prefers LESS-A? Patient preference might depend on their characteristics. Inoue et al. reported that female and young patients were more satisfied with LESS-A than with CLA, suggesting that LESS-A may be recommended for female and young patients [45]. At this time, it must be mentioned that a LESS-A indication should be comprehensively decided upon based on these factors since urologists have to be skilled while there is a certain demand for LESS-A.

## Comparison of LESS-A and CLA

A single-surgeon series of transperitoneal LESS-A compared to CLA demonstrated that LESS-A had better pain control, faster recovery of bowel function, and better cosmetic satisfaction than CLA, although the operative time was longer with LESS-A [46]. Wen et al. also reported a single-surgeon series of retroperitoneal LESS-A compared with conventional retroperitoneal adrenalectomy. They found that retroperitoneal LESS-A was superior in terms of postoperative hospital stay and

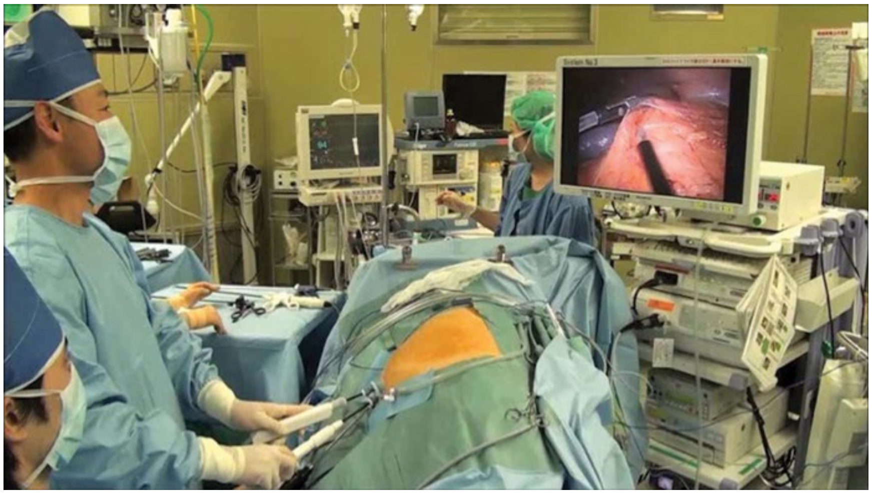

**Figure 111.8** In the crossover technique, the instrument in the surgeon's left hand is seen on the right side of the monitor, and that in the surgeon's right hand is seen on the left side of the monitor.

the time to resuming oral intake, although the operative time and opioid analgesic dosage were comparable [47].

A systematic review and meta-analysis comparing LESS-A and CLA revealed that operative blood loss and complications are similar, but that operative time seems to be longer in LESS-A. In addition, LESS-A has a shorter hospital stay after surgery and more acceptable perception of pain than CLA [48]. Another recent meta-analysis also suggests that LESS-A is a safe and feasible alternative to CLA due to its decreased postoperative pain, although the operative time is longer [49]. These results suggest that the operative time of LESS-A may be longer than that of CLA. Nevertheless, after a surgeon had experienced 30 cases of LESS-A, the pneumoperitoneum time was significantly decreased and the factors responsible for its prolongation had disappeared [43]. In summary, the technique for LESS-A, the crossover technique, appears to be not overly challenging but also not easy.

Hattori et al. compared 20 consecutive cases of LESS-A for pheochromocytoma with 30 cases of CLA for pheochromocytoma. They found no significant differences between LESS-A and CLA in terms of operation time, total fluid during the operation, estimated blood loss, first oral feeding, postoperative stay in the intensive care unit, and postoperative hospital stay. LESS-A could become one of the treatments of choice for resection of pheochromocytoma [50].

## Future perspectives

Since LESS-A first appeared, the instruments and techniques have been greatly improved. Bent instruments and sealing devices in particular have contributed to improving the operability and reducing the operation time. However, LESS-A is still not completely established. Lee et al. reported that they successfully carried out robotic single-site adrenalectomy using the da Vinci surgical system Si (Intuitive Surgical, Sunnyvale, CA, USA) [51]. The newest da Vinci surgical system, da Vinci Xi, has been designed for future techniques including single-site surgery. In the next decade, surgeons may face new challenges in adapting to new innovations in adrenal surgery.

## Anatomy

The seminal vesicles are paired tubular glands located superior to the prostate, posterior to the urinary bladder, and anterior to the rectum. Denonvilliers' fascia covers the posterior aspect of the seminal vesicles, separating the rectum from the bladder and prostate. Each vesicle forms as an outpocketing of the ampulla of its corresponding vas deferens, which is derived from the mesonephric duct. The excretory duct of each seminal vesicle joins the ipsilateral vas deferens to form the ejaculatory duct, which then enters the central zone of the prostate and opens to the urethra at the level of the verumontanum [1]. The vesiculodeferential artery – arising from the superior or inferior vesical arteries, which are branches of the internal iliac artery – provides the dominant blood supply to the seminal vesicle. The lymphatic drainage of the seminal vesicle is typically to the internal iliac lymph nodes [2].

Similar to its overall structure, a single tube folded and coiled upon itself, the lumen of the seminal vesicle is highly irregular. Histologically, the seminal vesicle is composed of mucosal and muscular layers. The convoluted mucosa consists of a pseudostratified columnar epithelium and underlying lamina propria, and the muscular layer consists of an inner circular and outer longitudinal layer of smooth muscle [3]. The secretions of the seminal vesicle are alkaline and comprise the majority of the ejaculate volume. Importantly, the seminal vesicle fluid contains factors necessary for sperm motility and survival, including fructose, prostaglandins, and coagulation factors [4].

## Pathology

### Benign disease

Benign diseases of the seminal vesicles include infection, stones, and cysts. Seminal vesicle amyloidosis has also been reported [5]. Infection of the seminal vesicles is more common in developing countries, as a result of tuberculosis and schistosomiasis [6, 7]. However, bacterial infection of the seminal vesicles may also occur as a result of instrumentation (e.g. during prostate biopsy), sexually transmitted diseases, or from a urinary source in an immunocompromised patient (Figure 112.1). Once the infection progresses to an abscess, surgical or percutaneous intervention is often required [8]. In the rare case of echinococcal disease involving the seminal vesicle, forming a hydatid cyst, treatment requires systematic antiparasitic medication, aspiration and injection of cysts with hydrogen peroxide and 10% formalin, followed by cyst excision [9].

Seminal vesicle calcifications (Figure 112.2) and stones may be a later sequela of infection and are associated with obstruction [10]. Intervention may be required for seminal vesicle stones associated with symptoms, such as chronic pelvic pain, hematospermia, ejaculatory pain, or infertility [11, 12].

Cysts of the seminal vesicle are rare, with estimated incidence of 1 out of 20 000 males [13]. Although typically asymptomatic, seminal vesicle cysts may cause pelvic pain, hematospermia, or urinary symptoms [14]. Congenital cysts occur as a result of Wolffian duct anomalies, and consequently are associated with ipsilateral renal abnormalities, such as agenesis or dysplasia,

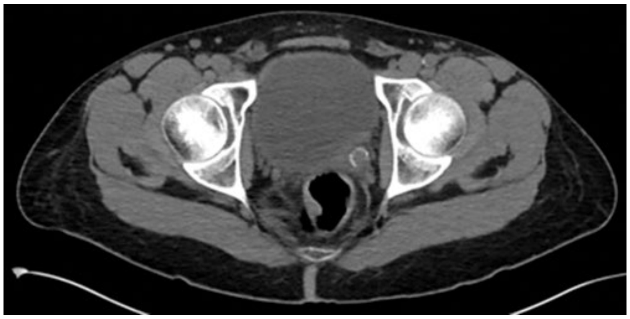

**Figure 112.2** Incidentally detected seminal vesicle calcification seen on CT scan.

polycystic kidney disease, ureteral ectopia, or ureterocele [13–16]. In the case of associated ejaculatory duct obstruction, the finding of unilateral renal agenesis and ipsilateral seminal vesicle cyst is termed Zinner syndrome [17]. Due to the close association with ipsilateral renal anomalies, the finding of a seminal vesicle cyst necessitates upper urinary tract imaging. Cysts of the seminal vesicle may also be acquired as a result of chronic ejaculatory duct or lower urinary tract obstruction [18, 19]. Surgical intervention is required in the case of superimposed infection and abscess (Figure 112.3), compression of urinary structures resulting in obstruction, or concern for malignant transformation [20–24].

## Benign tumors

Primary tumors of the seminal vesicle are rare, and include papillary adenoma and cystadenoma [25]. Schwannoma of the seminal vesicle has also been described [26]. Unlike malignant involvement of the seminal vesicle, benign tumors of the seminal vesicle demonstrate absence of adjacent organ involvement on imaging and do not cause elevations in serum tumor markers (e.g. prostate-specific antigen [PSA], carcinoembryonic antigen [CEA]) [27]. These tumors are often diagnosed due to symptoms, and pathologic diagnosis is made at the time of surgical excision [28]. Alternatively, if incidentally diagnosed and confirmed to be benign on biopsy, these tumors may be followed with serial transrectal ultrasound or cross-sectional imaging.

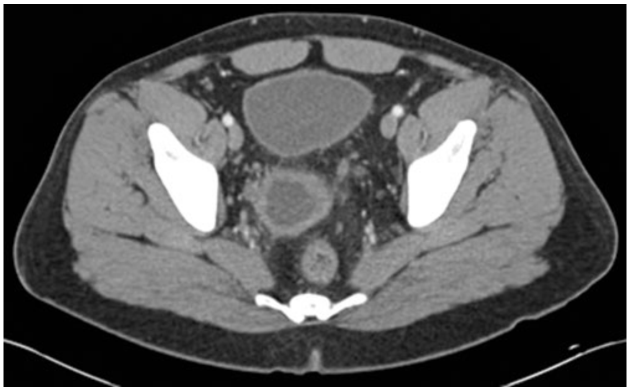

**Figure 112.3** Patient with history of seminal vesicle cyst found with an associated abscess on CT scan.

## Malignant tumors

Malignant involvement of the seminal vesicles from locally advanced pelvic tumors greatly outnumbers the frequency of primary malignancies of the seminal vesicles [29]. In the case of diagnostic uncertainty based on examination and imaging alone, serum tumor markers, cystoscopy, and/or sigmoidoscopy may be helpful in distinguishing prostate, bladder, or rectal carcinoma from a primary seminal vesicle malignancy. In the case of primary seminal vesicle malignancy, one would expect negative cystoscopic and sigmoidoscopic evaluations, normal PSA, normal CEA, and elevated cancer antigen 125 (CA-125) [30, 31].

Adenocarcinoma comprises the majority of malignant tumors of the seminal vesicle, with presenting symptoms including hematuria, hematospermia, dysuria, urinary retention, and rarely ureteral obstruction [29, 32]. In the case of advanced disease, pathologic diagnosis may be made by transrectal ultrasound-guided needle biopsy or transurethral resection. However, in the case of organ-confined disease on cross-sectional imaging, the pathologic diagnosis is often made at the time of surgical excision. Immunohistochemical profile includes positive CA-125, positive cytokeratin-7, and negative cytokeratin-20 staining [29–31]. In the case of CA-125-producing seminal vesicle carcinoma, the response to therapy may be monitored by serum CA-125 levels [31]. Other malignant tumors of the seminal vesicle include cystosarcoma phyllodes [33], sarcomas (rhabdomyosarcoma, leiomyosarcoma, and fibrosarcoma) [34, 35], extragastrointestinal stromal tumors [36], and primary germ cell tumors [37, 38]. Some have proposed that cystadenomas, cystosarcoma phyllodes, and sarcomas represent an increasingly aggressive spectrum of mixed epithelial stromal tumors [39].

## Diagnosis

### History and examination

The signs and symptoms of seminal vesicle pathology are vague and nonspecific; furthermore, seminal vesicle cysts and tumors may be completely asymptomatic. Reported symptoms, as described above, may include perineal or pelvic pain, pain with ejaculation, hematospermia, lower urinary tract symptoms, hematuria, infertility, and symptoms consistent with urinary tract obstruction. Physical examination of the seminal vesicles is limited. Digital rectal examination may be revealing in the case of infection or abscess due to exquisite tenderness, and a large seminal vesicle mass may be palpated. Urinalysis may reveal microscopic hematuria in some cases, prompting further evaluation with imaging and cystoscopy. Cystoscopic evaluation may reveal distortion of the ipsilateral trigone (i.e. asymmetric elevation of the trigonal ridge) or of the ipsilateral prostatic urethra [40].

### Imaging

Given the limitations of history and physical examination for seminal vesicle pathology, radiographic imaging is often necessary for accurate diagnosis. Transrectal ultrasound is the most commonly employed imaging modality for seminal vesicle pathology, and is the recommended initial study of choice for its cost, relative availability, and avoidance of ionizing radiation. The seminal vesicles are well visualized on transrectal ultrasound, and are normally symmetric, paired cystic structures located immediately superior to the prostate [41, 42]. Although cystic and solid components can be distinguished on ultrasound imaging, no specific imaging characteristics differentiate benign from malignant seminal vesicle tumors. This distinction can only be made with histopathology on either transrectal ultrasound-guided biopsy or surgical excision of the specimen. Secondary involvement of the seminal vesicle may be appreciated as lesions contiguous with the adjacent organ of primary disease, often affecting both seminal vesicles.

Cross-sectional imaging, either computed tomography (CT) scan or magnetic resonance imaging (MRI), provides greater anatomic information than transrectal ultrasound. The surrounding pelvic organs can be well visualized, and tissue planes between adjacent structures can also be delineated. On CT scan, cysts can be identified as well-defined structures filled with fluid (Hounsfield unit characteristics consistent with fluid). On MRI, cyst fluid would have high intensity on T2-weighted imaging, while hemorrhagic cysts would also have high intensity on T1-weighted imaging [42]. On both CT and MRI, abscesses would demonstrate rim-enhancement after administration of intravenous contrast and with surrounding soft tissue stranding. Neither imaging modality can reliably distinguish between benign and malignant tumors. Once again, this distinction can only be made with histopathology from either image-guided biopsy or surgical excision of the lesion. Obliteration of the surrounding tissue planes and involvement of both seminal vesicles may suggest secondary malignant involvement of the seminal vesicles from an adjacent tumor.

## Surgery

### Indications

Operative intervention of the seminal vesicles is indicated when any of the pathology discussed above (i.e. cyst, abscess, stone) becomes symptomatic or for tumors of the seminal vesicles. As transrectal ultrasound and cross-sectional imaging are unable to reliably differentiate benign from malignant tumors, accurate diagnosis requires surgical excision followed by histopathologic evaluation. Finally, surgical excision of the seminal vesicles is routinely performed during radical prostatectomy.

### Endoscopic interventions

For cases of seminal vesicle obstruction or cysts and abscesses near the prostatic urethra, transurethral resection of the ejaculatory ducts may provide decompression. Using a resectoscope and electrocautery or a rigid cystoscope with a holmium laser, the proximal verumontanum is excised until fluid is expressed. Care must be taken to remain distal to the bladder neck and proximal to the external sphincter. Although this approach has been shown to be effective for the treatment of seminal vesicle cysts and abscesses [43, 44], patients must be counseled on the risks of recurrence and infection, including epididymitis due to future on-going urinary reflux. Stones of the seminal vesicle can also be accessed in an endoscopic fashion by introducing conventional ureteroscopic instruments into the ejaculatory ducts [45].

### Laparoscopic or robotic approaches

Because of decreased postoperative pain, patient morbidity, and hospital length of stay compared to traditional open approaches [46, 47], laparoscopic (and robotic) approaches are the preferred method of seminal vesicle extirpative surgery. The laparoscopic approach to the seminal vesicles was first described in 1993 by Kavoussi et al. [48]. The transperitoneal route is utilized for isolated seminal vesicle surgery, while the retroperitoneal (extraperitoneal) route can be utilized during radical prostatectomy. Extraperitoneal access and port placement for laparoscopic radical prostatectomy is described elsewhere.

As with any abdominopelvic surgery under general anesthesia, deep vein thrombosis prophylaxis and appropriate antibiotics are administered prior to induction of anesthesia. The patient may remain supine with or without lower extremity spreader bars or the patient may be placed in lithotomy position. Importantly, the patient must be well secured to the operating room table as steep Trendelenburg position will be required to facilitate bowel mobilization out of the pelvis. A Foley catheter is placed to decompress the urinary bladder. Once the skin has been shaved and prepped, pneumoperitoneum is established with Veress needle or Hasson technique, and the 10 mm port is placed 1–2 fingerbreadths above the umbilicus. After adequate pneumoperitoneum is ensured and the underlying bowel is examined for injuries under direct visualization using the laparoscope, two 5 mm (8 mm in the case of robot-assistance) working ports are placed inferolaterally, at least 8 cm on either side of the 10 mm port, at the level of the umbilicus. In the case of robot-assistance, an additional 8 mm port and 12 mm port may be placed 8 cm lateral to either working port at the level of the umbilicus. For the nonrobotic laparoscopic approach, assistant ports should include a 12 mm port placed 8 cm lateral to the right working port at the level of the umbilicus and a 5-mm port placed superolaterally to the camera port (Figure 112.4).

Once the ports are placed, the patient is put into steep Trendelenburg position. In the case of robot-assistance, the robot is docked and instruments are placed, typically monopolar scissors in the robot one arm, bipolar Maryland forceps in the robot two arm, and ProGrasp® forceps in the robot three arm [49, 50]. The assistant uses the suction–irrigator and provides countertraction when necessary, and uses the clip-applier through the 12 mm port. For traditional laparoscopic surgery, the surgeon may use a variety of energy sources. Although the authors prefer to use monopolar scissors and bipolar Maryland forceps, the use of a harmonic scalpel or laparoscopic LigaSure™ may also be considered. Lysis of adhesions is performed, and the sigmoid colon is mobilized out of the pelvis and retracted with the robotic fourth arm or by the assistant. The peritoneal fold at the junction of the rectum and bladder is noted (i.e. the peritoneal cul-de-sac), and the peritoneum is incised at the midline in a transverse fashion (Figure 112.5). The seminal vesicles or vas are identified with a combination of sharp and blunt dissection. If these structures are not readily apparent, the ipsilateral vas can be traced from the inguinal ring as it crosses below the medial umbilical ligament and over the ureter. Once the vas is identified, it is retracted medially and divided without extensive lateral dissection to avoid potential ureteral injury (Figure 112.6). Particularly in the case of a large seminal vesicle mass that extends laterally, the use of temporary ureteral catheters or double-J stents may be beneficial to reduce the risk of ureteral injury. The vas is retracted in a medial and cranial direction to bring the seminal vesicle into the operative field. Combination blunt and sharp dissection is performed on the seminal vesicle circumferentially and strictly on the plane of the seminal vesicle. Dissection proceeds in a medial to lateral direction (Figure 112.7). Continuous adjustment of retraction to ensure medial and cranial force on the seminal vesicle is important, as care must be made to avoid injury to the neurovascular bundle or the ureter, which lie near the lateral tip of the seminal vesicle. The dominant blood supply to the seminal vesicle is also located in this region: the vesiculodeferential artery

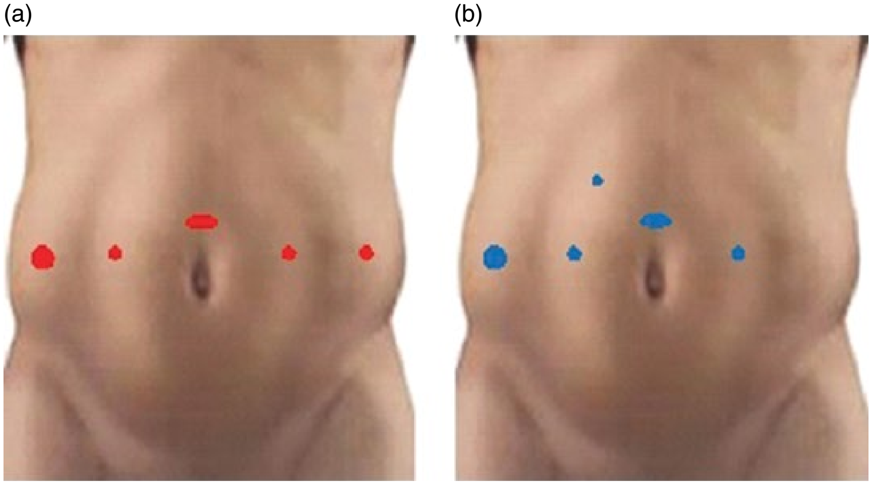

**Figure 112.4** Port configuration for robot-assisted (a) and traditional laparoscopic (b) approaches to the seminal vesicle. Please see text for port sizes and relative distances from one another.

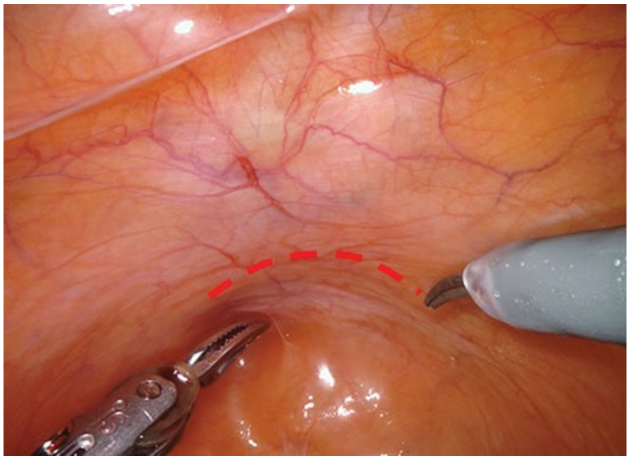

**Figure 112.5** Appearance of the pelvic peritoneal fold and location of incision to approach the seminal vesicles from a transabdominal laparoscopic (or robotic) approach (red dashed line).

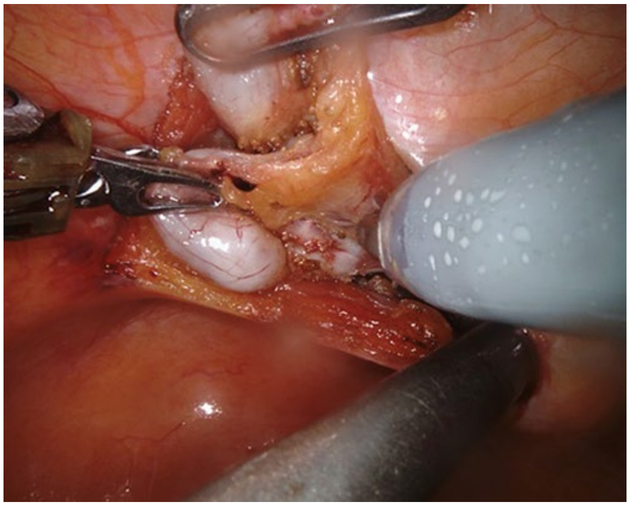

**Figure 112.7** Dissection of the right seminal vesicle with the right vas retracted medially and superiorly.

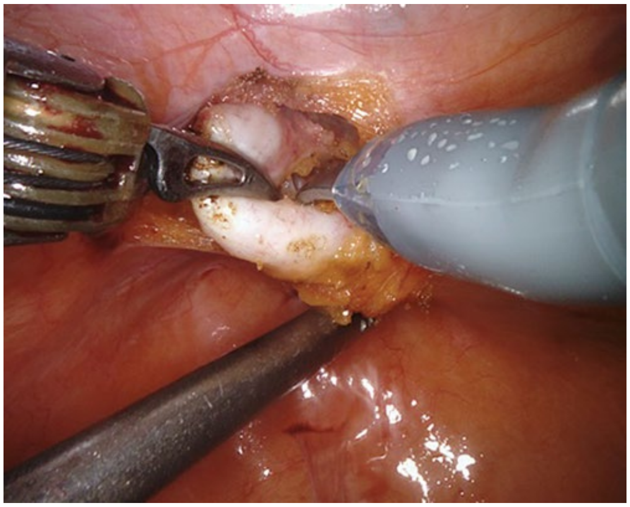

**Figure 112.6** Dissection of right vas deferens prior to division.

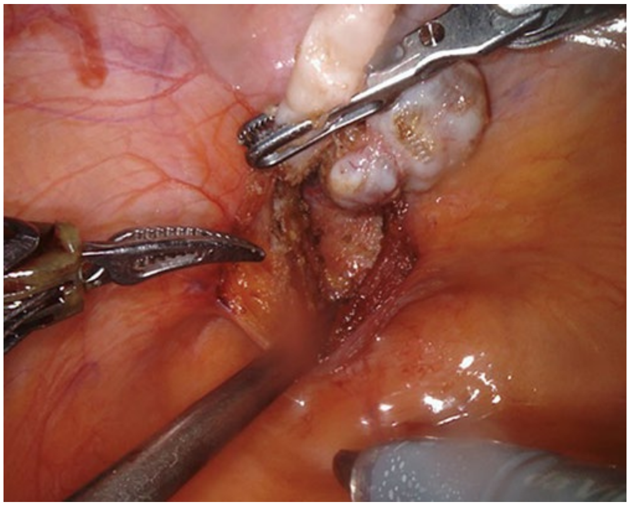

**Figure 112.8** Completed dissection of the right seminal vesicle and vas.

typically arises from the inferior vesical artery, which is a branch of the internal iliac artery. These vessels may be divided with clips or with judicious electrocautery.

Once the seminal vesicle and vas have been completely dissected (Figure 112.8), the ejaculatory duct may be transected at the entrance to the prostate. Plication of the prostatic tissue on either side of the ejaculatory duct may be performed but is not imperative. In patients with seminal vesicle cysts who desire fertility preservation, the seminal vesicle can be dissected without division of the ipsilateral vas deferens, and the cyst can be divided at its base with reapproximation of the seminal vesicle defect. The specimen is placed in an Endo Catch™ bag and extracted through either the midline camera port or the lateral assistant port. Some recommend reapproximation of the overlying peritoneum, but this is not absolutely necessary. The 10 and 12 mm port sites should be closed with 0 Vicryl suture, and the skin incisions reapproximated with absorbable suture, staples, or skin glue. The patient should be observed overnight, with diet advanced as tolerated. Foley catheter can typically be removed the following morning, except in the case of large prostatic defect with urethral exposure or entry.

## Conclusions

Various seminal vesicle pathologies exist that require surgical intervention. Although diagnostic imaging may provide insights, histopathology is required to differentiate benign from malignant tumors. In these cases, laparoscopic (or robotic) approaches are preferred.

# Modern Techniques in Abdominal Wall Hernia Repair: a Guide for the Practicing Endourologist

*Douglas K. Held*

*Northwell Health Long Island Jewish Medical Center, New Hyde Park, NY, USA*

## Introduction

Abdominal wall hernias are the most common surgical condition for which patients seek care. In the current healthcare environment, a significant proportion of general surgical practice is devoted to the repair of hernia. The last three decades have witnessed significant advancements in both surgical technique and prosthetic implants to aid the hernia surgeon. As in other specialized fields of medicine, there are now centers of excellence devoted to both complex abdominal wall reconstruction and the study of the physiology of the abdominal wall.

The use of prosthetic materials in hernia repair has become ubiquitous throughout the United States and Europe. In short, the mesh implant industry has grown to a 1 billion dollar plus business with some individual prosthetics costing in excess of US$10 000 [1]. From a surgical perspective, an experienced well-trained "herniologist" should be able to perform both laparoscopic and open techniques. There is no longer a one-size-fits-all approach. A hernia specialist should be able to evaluate the patient and decide on either a laparoscopic or open approach with consideration given to complicating medical issues, technical factors, and cosmesis. One thing has become very clear in the management of abdominal wall hernia – the use of mesh implants has decreased the rate of recurrence, but has simultaneously introduced a range of potential complications.

From the standpoint of the practicing endourologist, there will be preoperative considerations in performing laparoscopic/robotic procedures in patients with existing hernia. This will require management of both abdominal adhesions and trocar placement with consideration to simultaneous repair of the hernia itself. The remainder of this chapter will be devoted to current laparoscopic techniques utilized in some of the more common hernias of the abdominal wall.

## Laparoscopic techniques

As part of the patient's medical history, the endourologist should be cognizant of both the patient's surgical history and the presence of abdominal wall hernia. If there is a plan to repair the hernia, the surgeon should have a working knowledge of the types of mesh prosthetics currently in use and be familiar with potential complications of mesh implantation. There are currently both biologic and synthetic meshes available for use in repair of abdominal wall defects (Tables 113.1–113.3).

## Technical principles

Every hernia of the abdominal wall has one common denominator: a musculofascial defect through which abdominal contents or preperitoneal structures can herniate. The repair of the musculofascial defect has evolved over the last century in an attempt to decrease postoperative discomfort, provide earlier return to activity, and decrease the rate of recurrence. The repair of inguinal, incisional/ventral, and parastomal hernias all require the defect either be closed primarily, bridged with a prosthetic, or most commonly, a combination of primary closure with prosthetic reinforcement.

Surgical literature has clearly shown that the use of mesh implants decrease the overall rate of recurrence [2, 3]. In addition, especially in dealing with midline defects, it is preferred to restore continuity of the musculature by

**Table 113.1** Synthetic mesh implants commonly used in hernia repair.

| | Commercial mesh name | Material | Manufacturer |
|---|---|---|---|
| 1. | Vicryl™ Woven Mesh | Polyglactin 910 (polyglycolic acid) | Ethicon (Somerville, NJ, USA) |
| 2. | PROLENE™ 3D Patch Polypropylene Mesh | Polypropylene | Ethicon |
| 3. | PROLENE™ Polypropylene Mesh | Polypropylene | Ethicon |
| 4. | PROLENE™ Polypropylene Hernia System | Polypropylene | Ethicon |
| 5. | MERSILENE™ Polyester Fiber Mesh | Polyethylene terephthalate | Ethicon |
| 6. | ULTRAPRO™ Partially Absorbable Lightweight Mesh | Monocryl (poliglecaprone 25) and polypropylene | Ethicon |
| 7. | ULTRAPRO™ Plug | Monocryl (poliglecaprone 25) and polypropylene | Ethicon |
| 8. | ULTRAPRO™ Hernia System | Monocryl (poliglecaprone 25) and polypropylene | Ethicon |
| 9. | PVP™ Device | Oxidized regenerated cellulose (ORC) and polypropylene | Ethicon |
| 10. | PROCEED™ Surgical Mesh | Oxidized regenerated cellulose (ORC) and polypropylene | Ethicon |
| 11. | Parietex™ Composite (PCO) Mesh | Macroporous polyester, with a 3D weave material with resorbable collagen film | Covidien (Mansfield, MA, USA) |
| 12. | Parietex™ Composite Open Skirt (PCO OS) Mesh | Macroporous polyester, with a 3D weave material *with* resorbable collagen film | Covidien |
| 13. | Parietex™ Composite (PCO) Parastomal Mesh | Macroporous polyester, monofilament material | Covidien |
| 14. | Parietex™ Composite (PCO) Hiatal Mesh | Macroporous polyester, with a 3D weave material *with* resorbable collagen film | Covidien |

**Table 113.2** Current biologic implants used most often in infected wounds but used rarely for noninfected primary hernia repairs.

| Product and origin | Manufacturer |
|---|---|
| Alloderm (cadaveric dermis) | Lifecell, Branchburg, NJ, USA |
| AlloMax (cadaveric dermis) | CR Bard, Providence, RI, USA |
| CollaMend (porcine dermis) | CR Bard, Providence, RI, USA |
| FlexHD (cadaveric dermis) | Ethicon Inc., Somerville, NJ, USA |
| Permacol (porcine dermis) | Covidien, Mansfield, MA, USA |
| Strattice (porcine dermis) | Lifecell, Branchburg, NJ, USA |
| SurgiMend (fetal bovine pericardium) | TEI Biosciences, Boston, MA, USA |
| Surgisis (porcine small intestinal submucosa) | Cook Medical, Bloomington IN, USA |
| Veritas (bovine pericardium) | Synovis, St. Paul, MN, USA |
| XenMatrix (porcine dermis) | CR Bard, Providence, RI, USA |

direct suture or with some form of myofascial release, facilitating midline closure. It is clear that most forms of direct closure will place tension across the wound even with fascial release procedures. For this reason, it is proper to reinforce the closure with some form of prosthetic "buttress."

Prosthetics used in hernia repair have evolved rapidly over the last 20 years. The use of polypropylene mesh for abdominal wall closure was first reported in 1962, and for many years was the only viable option in hernia repair [4]. The material elicits a strong inflammatory reaction in the surrounding tissues, with scar plate formation.

It soon became apparent that although mesh implants decreased overall hernia recurrence rates, the use of plain, heavyweight polypropylene created potential problems. If polypropylene is placed in an intra-abdominal location, it can cause severe inflammatory reaction in adjacent organs, leading to dense impenetrable adhesions with potential erosion and fistula formation. In addition, the use of mesh or foreign material in any form can exacerbate wound infection and can

**Table 113.3** Results of biologic implant usage in difficult wounds.

| Product | Description | Overall complication rates | Recurrence rates | Rates of postoperative infection | Need for explantation |

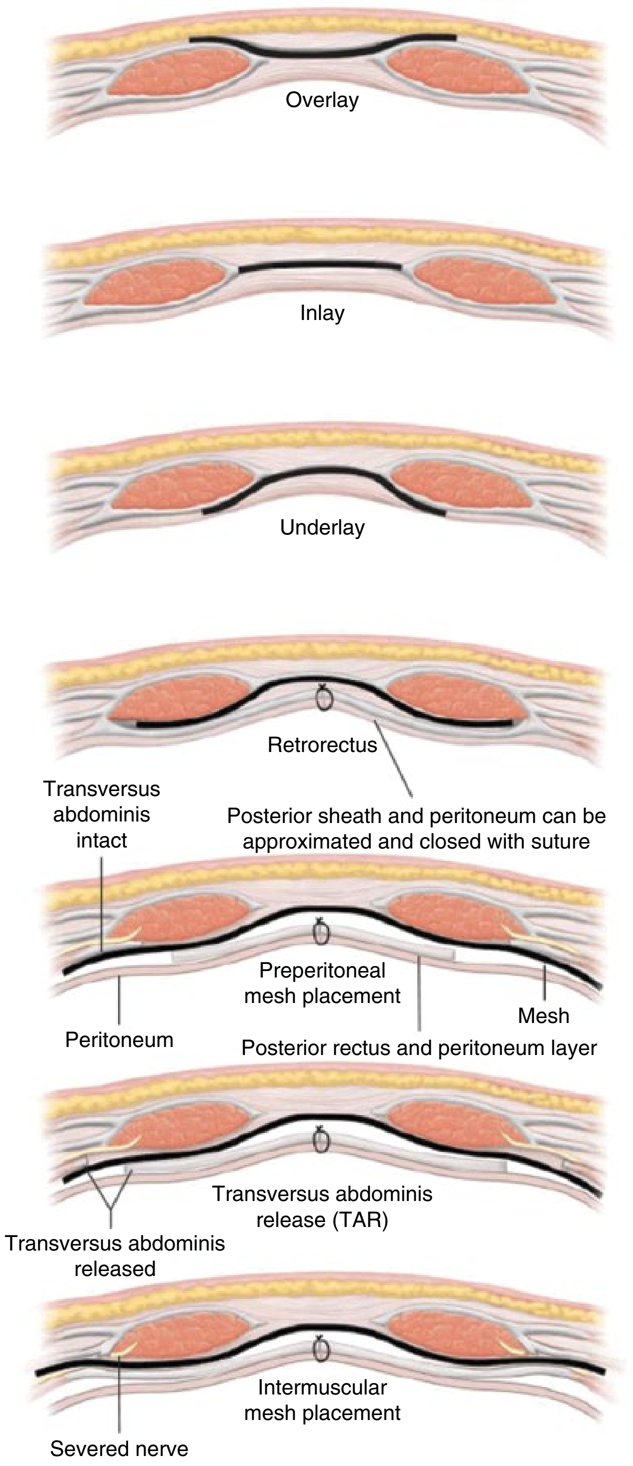
necessitate removal with potential catastrophic results. Often this requires multiple surgical procedures for resolution.

With consideration of these findings, prosthetic research and development has evolved with the following principles:

- Tensile strength must be maintained to avoid prosthetic rupture.
- An adhesive barrier should be placed for potential use in any intra-abdominal location adjacent to viscera.
- Implants should be designed for easy deployment using either open or laparoscopic techniques.
- Potential resistance to infection should be considered.
- Using prosthetic material which contracts over time can be a source of abdominal pain and lead to recurrent herniation.

The technical aspects of mesh placement have also been studied carefully with reference to the rate of recurrence and complications.

- Mesh can be placed intraperitoneally, preperitoneally (retromuscular), or as an onlay over the muscular closure (Figure 113.1).
- It is imperative to overlap the defect by at least 4–6 cm in all directions.



Overlay
Inlay
Underlay
Retrorectus
Transversus abdominis intact
Posterior sheath and peritoneum can be approximated and closed with suture
Preperitoneal mesh placement
Mesh
Peritoneum
Posterior rectus and peritoneum layer
Transversus abdominis release (TAR)
Transversus abdominis released
Intermuscular mesh placement
Severed nerve

**Figure 113.1** Various locations of mesh placement.

- Depending on location, the mesh must be fixed to the abdominal wall with sutures, staples, fibrin glues, or the use of self-fixating mesh.
- Inlay techniques that do not overlap the repair, but merely bridge the defect should be avoided.

## Laparoscopic repair of incisional/ventral abdominal wall hernias

### Incisional hernia

Incisional hernias can develop in any region of the abdominal wall where previous fascial closure has been performed. The incidence of the midline hernia has been reported to be 11–23% after midline laparotomy [5]. Causes of incisional hernia are most often a combination of technical and patient-related factors. Wound infection, obesity, smoking, and malnutrition are the most common related factors in incisional hernia occurrence. Correct technique in fascial closure is imperative. It is important for the laparoscopic surgeon to note that incisional hernia can develop in port sites, most commonly when 10 mm or larger ports are used. It is not clear from the literature that fascial closure of 10 mm or larger port sites decreases the incidence of hernia, but generally, most surgeons advocate fascial closure both in the midline and laterally, especially below the semilunar line.

#### Preop consideration

As stated previously, there are two aspects to consider when performing a laparoscopic urologic procedure in patients with concurrent ventral hernia. Is the hernia within the surgical field of the proposed urologic procedure? Will it present a hazard secondary to adhesions and the presence of incarcerated structures? This can be defined with preoperative contrast computed tomographic (CT) scans if necessary. At our institution, general surgery is often consulted preoperatively and simultaneous repair of the hernia is often completed at the time of the urologic procedure. In fact, smaller ventral hernia sites have been used to extract the operative specimen followed by open repair of the hernia.

#### Laparoscopic repair

Laparoscopic repair of incisional hernia should be performed selectively based on the size of the defect and its location. In a general sense, the larger the defect the more difficult it is to restore muscular continuity and provide a symmetrical appearance of the abdominal wall with relief of symptoms.

We employ laparoscopic repair most often in patients with smaller defects where the defect is bridged and overlapped, but the defect itself is not closed. With proper patient selection, this will provide symptomatic relief and prevent incarceration of the hernia.

Technically, access to the abdominal cavity is chosen at a site remote from the defect, allowing for visualization of the defect and its contents (Figure 113.2).

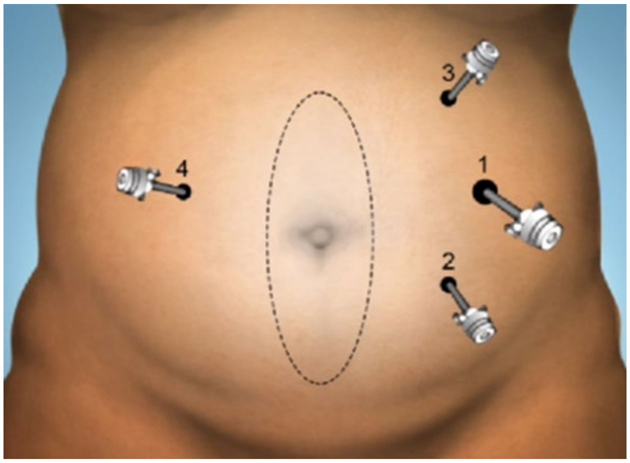


**Figure 113.2** Port placement for midline incisional defect.

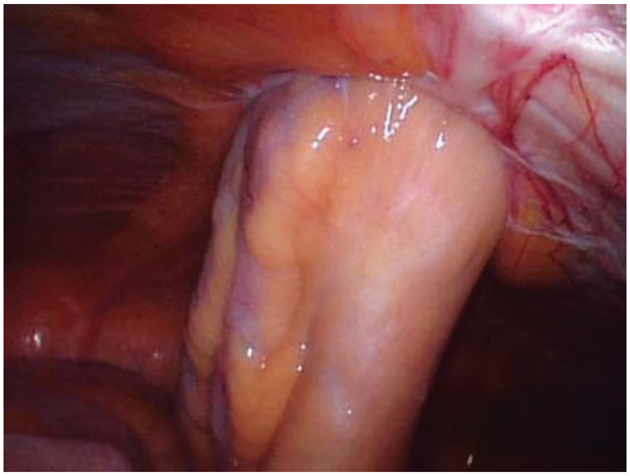

**Figure 113.3** Incarcerated incisional hernia.

We generally employ a 5 mm, 30°, or 0° scope which can be placed initially in the access site and can be rotated to any working port to facilitate dissection and mesh placement. After initiation of pneumoperitoneum and placement of working ports the defect is inspected, complete reduction of hernia contents (Figure 113.3) and lysis of adhesions is initiated, and adequate clearance of the surrounding abdominal wall is assured (Figure 113.4). The hernia sac is generally left in place and the inner dimensions of the defect are measured with a flexible ruler placed intra-abdominally. A prosthetic barrier-type mesh is chosen to overlap of the defect by 6 cm in all directions. Multiple stay sutures of 0 long-term dissolvable material are used circumferentially at the edge of the defect (Figure 113.5). The mesh is then introduced through the access site and placed under the defect. A suture assist device is used through minute incisions in the abdominal wall to elevate the mesh and ensure adequate overlap of the defect. The stay sutures are tied beneath the small incisions in the subcutaneous tissue and the mesh is elevated to the peritoneal surface (Figure 113.6).

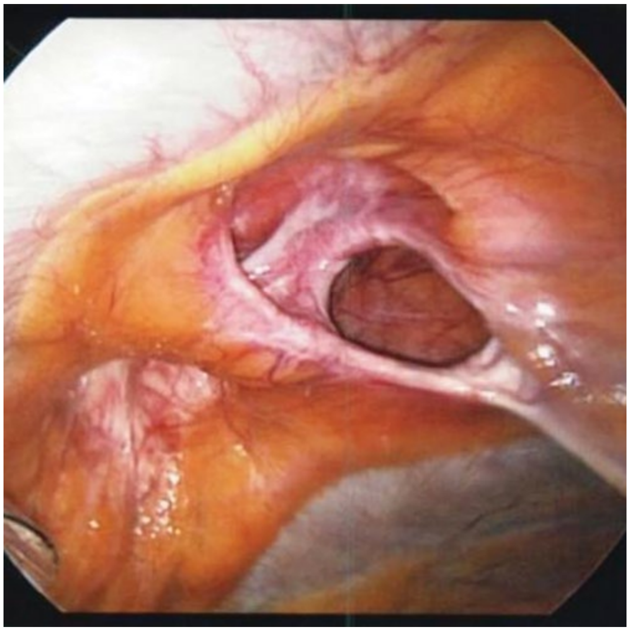

**Figure 113.4** Defect after reduction and enterolysis.

Additional fixation is then commenced with a surgical tacker with at least three rows of long-term dissolvable tacks placed around the material in the abdominal wall (Figure 113.7). This is generally completed with a reduced intra-abdominal pressure of 8–10 mmHg. Reducing the pressure helps to ensure flush contact with the peritoneal surface and minimizes redundancy and buckling of the material. It is imperative to make sure that the barrier side is facing the viscera and that the mesh edges are secured, preventing the viscera from herniating between the mesh and the abdominal wall. The trocars are then removed and an abdominal binder is placed to theoretically reduce seroma formation and promote adherence of the hernia sac.

### Other laparoscopic techniques

Recent advances in laparoscopic technique, including robotic surgery, have introduced modifications to the preceding technique with attention to repair of large defects and closure of the abdominal musculature. This is based on improvements in intracorporeal suturing technique and abdominal wall myofascial flap release procedures. Ramirez et al. first described the technique of component separation where the anterior rectus fascia is incised lateral to the semilunar line on one or both sides of the midline [6] (Figure 113.8). Laparoscopically assisted component separation is a technique employing a myofascial advancement flap, whereby muscular closure can be

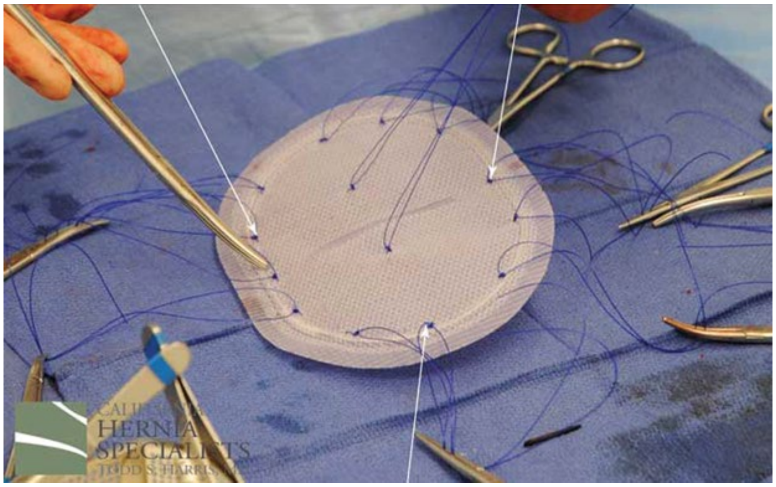

**Figure 113.5** Placement of stay sutures in mesh. The appropriate size mesh is selected for the particular patient. Sutures are placed at intervals around the mesh. These sutures ultimately will be brought through the muscle to secure the mesh in place under the newly repaired muscle wall.

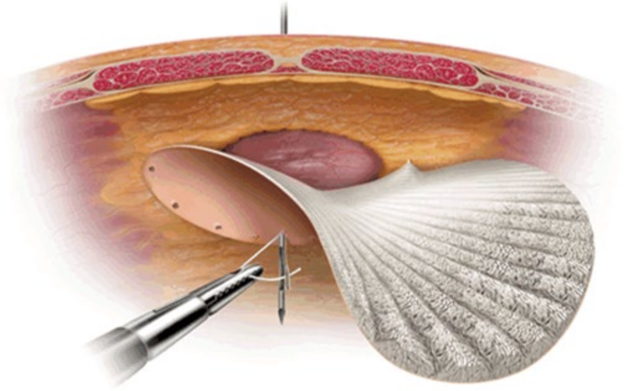

**Figure 113.6** Mesh fixation to abdominal wall.

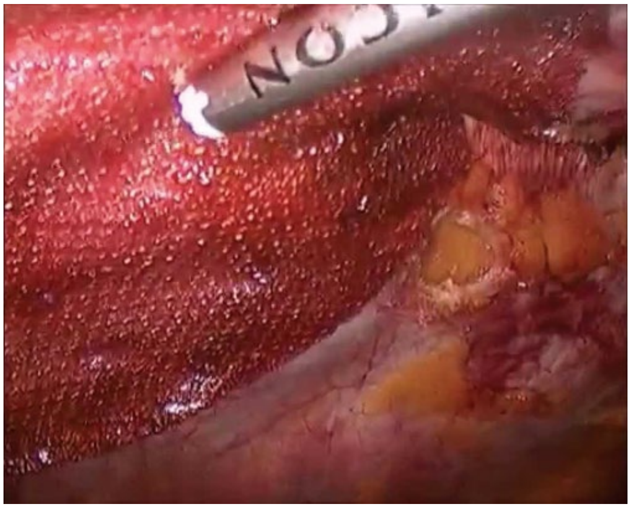

**Figure 113.7** Reinforcement of mesh to abdominal wall with tacks.

accomplished in the midline [7]. This technique can add as much as 20 cm advancement to facilitate midline muscular closure [8]. After closure, mesh reinforcement of the repair is generally used to buttress the closure. If done open, the mesh can be placed as a sublay, in the retromuscular (retrorectus) position, or as an onlay. Laparoscopically, the options are retromuscular or as a sublay.

### Results

In general, over the last quarter century, there has been vast improvement in both functional and cosmetic results of ventral hernia repair. The most significant parameters of improvement are the lower rates of recurrence in both open and laparoscopic repairs utilizing mesh. In addition, reestablishing continuity of the abdominal musculature and the ability to manage large defects improve symptoms and functional results. When evaluating results, it is clear that there is no current consensus on one particular methodology.

As stated, multiple series in the literature have clearly confirmed the superiority of mesh repair when compared to simple suture with respect to recurrence. It is important to note that although mesh repair has decreased overall rates of recurrence, hernias can recur up to 10 years after the original repair [9]. Especially in large, >10 cm defects, even repairs with mesh have been reported to recur in as many as 20% of patients. The increased use of myofascial advancement, although yielding superior cosmetic and functional results, has not been shown to be superior to other mesh techniques with regard to recurrence [10].

### Laparoscopic versus open technique

Multiple randomized trials have demonstrated that the laparoscopic technique has low rates of wound infection when compared to the open technique. Importantly, the

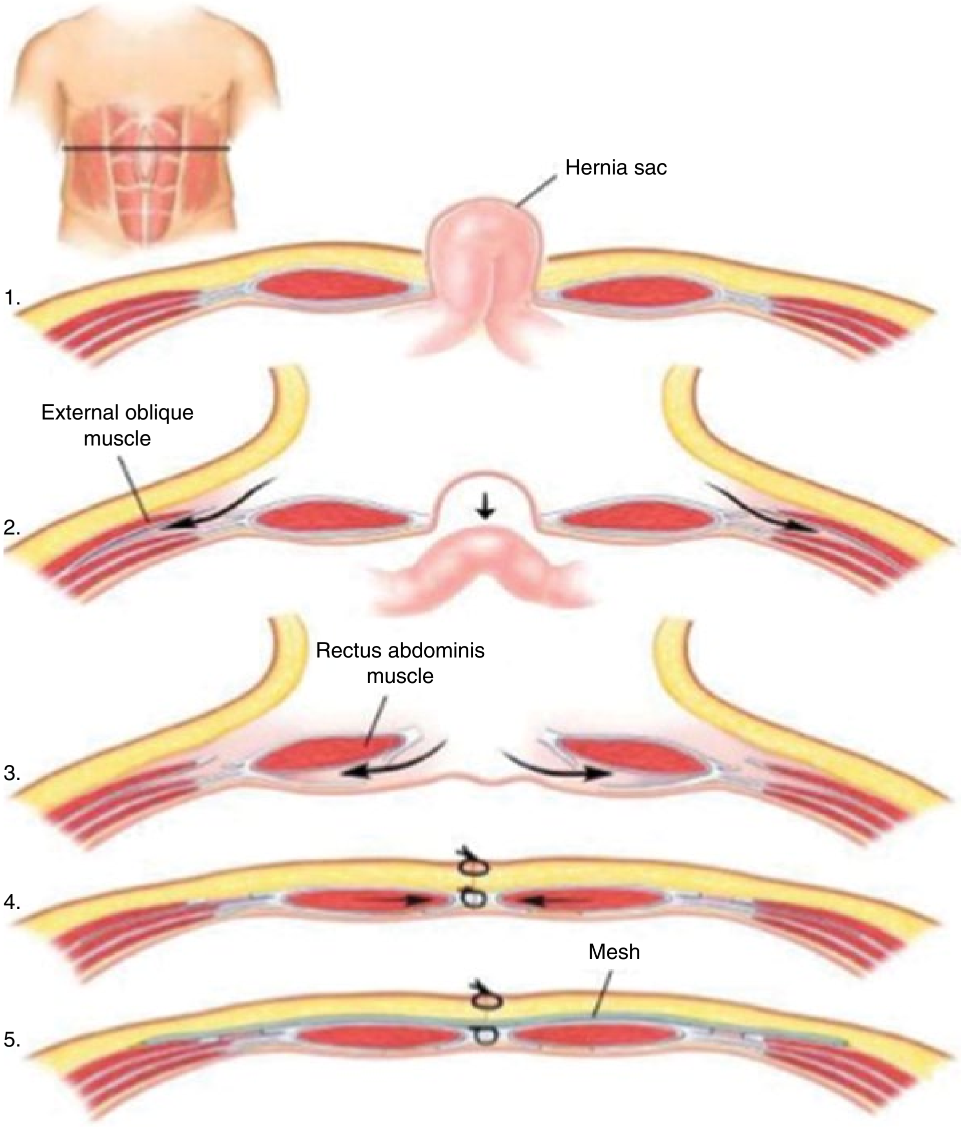

**Figure 113.8** Component separation to facilitate midline muscular closure.

rate of complications, including bowel obstruction in addition to rates of recurrence, shows no statistical difference. Of note, the incidence of bowel injury is higher in the laparoscopic repair group [11] (Table 113.4).

### Complications of laparoscopic surgery

Wound seroma is a common result of laparoscopic repair which generally occurs between the mesh and retained hernia sac. In the vast majority of cases, these will resolve spontaneously with no sequelae. General avoidance of drainage is preferred to mitigate the potential for wound infection. In symptomatic collections, after adequate skin preparation, the fluid can be drained with direct needle puncture. In rare cases, ultrasound guidance may be necessary (Figure 113.9).

Wound infection, generally the most feared result in any procedure requiring implants, is a rare complication of laparoscopic ventral hernia repairs. Wound infection when prosthetic material is exposed often requires explantation of the material. If PTFE is used, generally, implant removal is required. Infections in derivatives of polypropylene mesh or polyester mesh can sometimes be managed with drainage and antibiotics without removal of the material.

### Bowel injury

Laparoscopic repair can often require extensive enterolysis for reduction of incarcerated hernia contents. In the course of enterolysis inadvertent enterotomy can occur. Once recognized and repaired, there are a number of

**Table 113.4** Comparative meta-analysis comparing laparoscopic versus open repair for incisional hernia.

| Outcomes | No. of studies | No. of patients | HG, $\chi^2$ | HG, *P* value | Model | RR/WMD | *P* value | 95% CI |

options to consider. If the contamination is significant it is generally preferred not to place an implant. In which case, the procedure can be abandoned and the patient can be brought back to surgery at a later date.

As with all laparoscopic procedures, unrecognized bowel injury is a potential devastating complication. In any procedure where extensive enterolysis has been performed, it is imperative to pay attention to the patient's complaints of pain and anorexia. Postoperative temperature elevations and tachycardia are significant findings and often should be worked up with early postoperative CT scans. The presence of free fluid, free air, and/or ileus should alert the clinician to the possibility of bowel injury. If suspected, immediate surgical intervention is required.

## Inguinal hernia

Hernias of the inguinal region are extremely common and have a reported incidence of up to 25% in males. Over the last quarter century, improvements in inguinal hernia repair have focused on three main factors: less postoperative discomfort, early return to full activity, and decreased rate of recurrence. The use of prosthetics in both open and laparoscopic inguinal hernia repairs has become extremely popular. The routine use of mesh in primary open inguinal hernia was strongly advocated by Lichtenstein et al. in the 1990s [12]. The technique includes reduction of the hernia sac, closure of the defect in the transversalis fascia, and onlay mesh to cover the pubic tubercle and entire inguinal floor (Figure 113.10). There are many current derivatives of the above

technique including the Bard PerFix® Plug (CR Bard, Murray Hill, NJ, USA), which is placed in the defect and sutured to the transversalis fascia with an onlay over the inguinal floor (Figures 113.11 and 113.12). In addition, the Ethicon Prolene® hernia system, with combined preperitoneal and onlay patches, has also become popular (Figure 113.13).

As in repair of incisional/ventral defects, there is no generally accepted preferred method of inguinal repair. Only one caveat applies, the rate of recurrence should be comparable in the evaluation of different techniques. In high-volume centers and individual practices, the rate of recurrence should be comparable in either open or laparoscopic repairs and should clearly be under 5%. The decision to perform either open or laparoscopic repair is essentially up to the operating surgeon. It is not clear from the literature that laparoscopic repair for unilateral inguinal hernia offers superior results with respect to early recovery and recurrence rates. Therefore, many surgeons will perform open repair for unilateral hernia, reserving the laparoscopic approach for bilateral hernia and recurrences. Large or incarcerated inguinal hernias can be difficult to perform laparoscopically and are therefore done open or with an intraperitoneal laparoscopic technique. In addition, previous lower midline abdominal surgery can make laparoscopic repairs difficult.

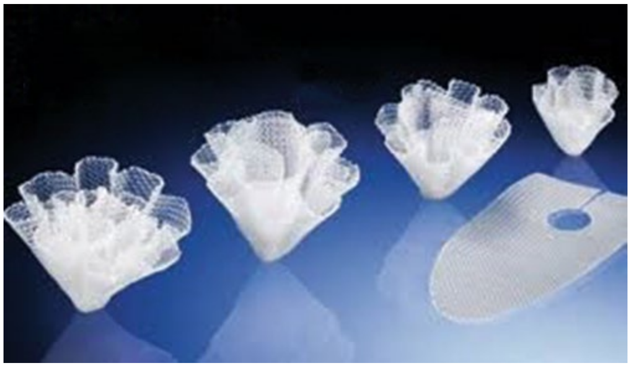

**Figure 113.11** Bard PerFix® Plug.

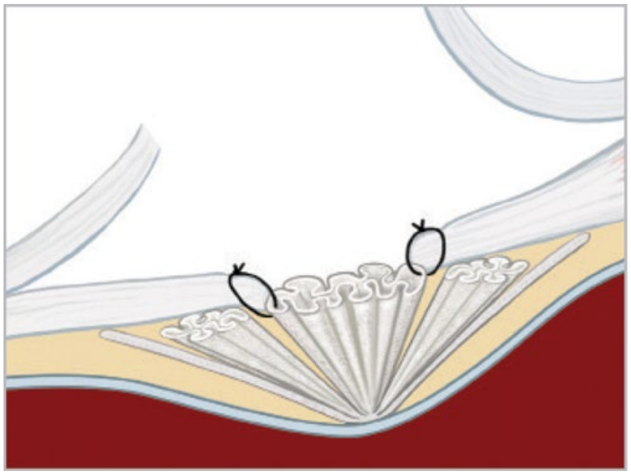

**Figure 113.12** Placement of plug through defect in transversalis fascia.

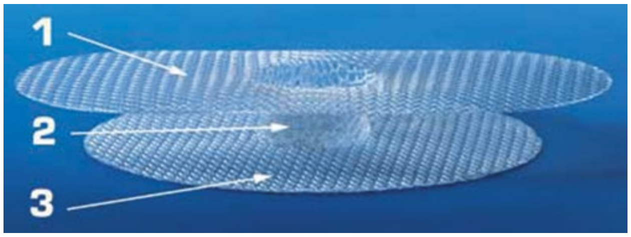

**Figure 113.13** Prolene hernia system: 1. Onlay patch, 2. connector, 3. sublay patch.

There are two popular types of laparoscopic repair currently in use. Total extraperitoneal (TEP) repair and transabdominal preperitoneal (TAP) repair both employ a mesh prosthetic placed in the preperitoneal space and therefore isolated from the viscera. A third technique involving intraperitoneal onlay mesh (IPOM) is also a viable technique, but somewhat less popular today.

For the TEP repair, the patient is given a general anesthetic, use of a Foley catheter is optional, although we have patients void just prior to entering the operating room. An incision is made in the infra-umbilical region and carried down to the anterior rectus fascia. On either side of the midline, an incision is made in the anterior fascia with elevation of the rectus muscles and exposure of the preperitoneal space. A balloon dilator is placed up to the pubis and inflated, thereby creating the working space for the repair (Figure 113.14). In general, two working ports are placed.

The hernia is identified (femoral, direct or indirect), reduced, and a mesh is then placed preperitoneally (Figure 113.15). The mesh is then fixed to the abdominal wall either with dissolving tacks or fibrin glue (Figure 113.16). With tack fixation, care is taken to avoid the triangle of doom and triangle of pain (Figure 113.17). At completion of the procedure, the pneumoperitoneum is evacuated with collapse of the preperitoneal space.

The TAP procedure is essentially similar to the TEP procedure and is only different in that access to the preperitoneal region is gained transabdominally. The peritoneum is incised over the myopectineal orifice, the mesh is placed and secured with closure of the peritoneal opening.

From the perspective of the endourologist, inguinal hernia will rarely complicate the genitourinary procedure being performed. Consideration may be given to simultaneous repair of the hernia at the time of the urologic surgery.

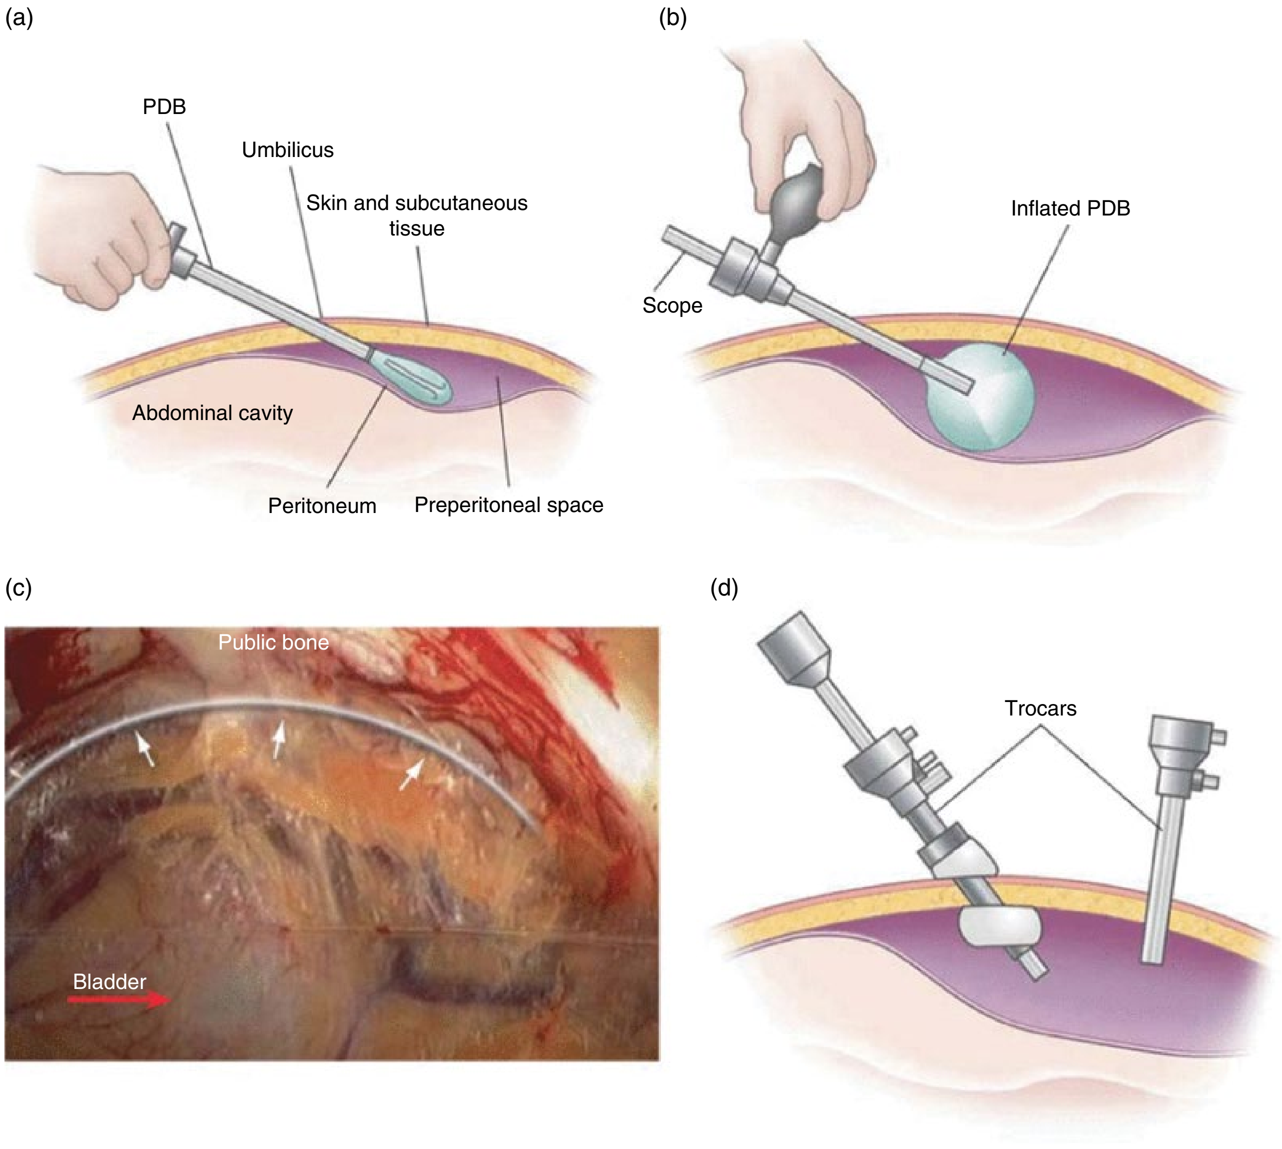

**Figure 113.14** Preperitoneal balloon dilator (PBD) and placement of working ports for total extraperitoneal (TEP) repair.

### Results of laparoscopic technique

With respect to repair of inguinal hernia, multiple series comparing laparoscopic to open techniques, and comparison of TEP and TAP repairs are reported. In general, series which compare open and laparoscopic techniques conclude that laparoscopic repairs have a slightly higher rate of recurrence. In 2012, a data analysis confirmed that there is a slightly higher recurrence rate in laparoscopic repairs compared to open repairs. In addition, TEP repairs were found to have a slightly higher recurrence rate than TAP repairs [13].

### Complications specific to laparoscopic repair

As in other minimally invasive procedures, there are complications unique to the laparoscopic approach. These are related both to mesh placement and the exposure necessary to complete the repair. Complications of laparoscopic inguinal herniorrhaphy occur in up to 13% of cases [14]. It is imperative that the surgeon has a full working knowledge of the preperitoneal anatomy of the groin. Injury to the femoral vein, iliac vein, and epigastric vessels have all been reported with potentially catastrophic consequences. In addition, injury to the femoral branch of the genitofemoral nerve, lateral femoral cutaneous nerve, and femoral nerve have all been reported. Small bowel obstruction after laparoscopic repair has been reported primarily due to two main factors: exposed mesh within the peritoneal cavity creating adhesions and entrapment of bowel within a peritoneal defect created at the time of the repair. As discussed previously, trocar site

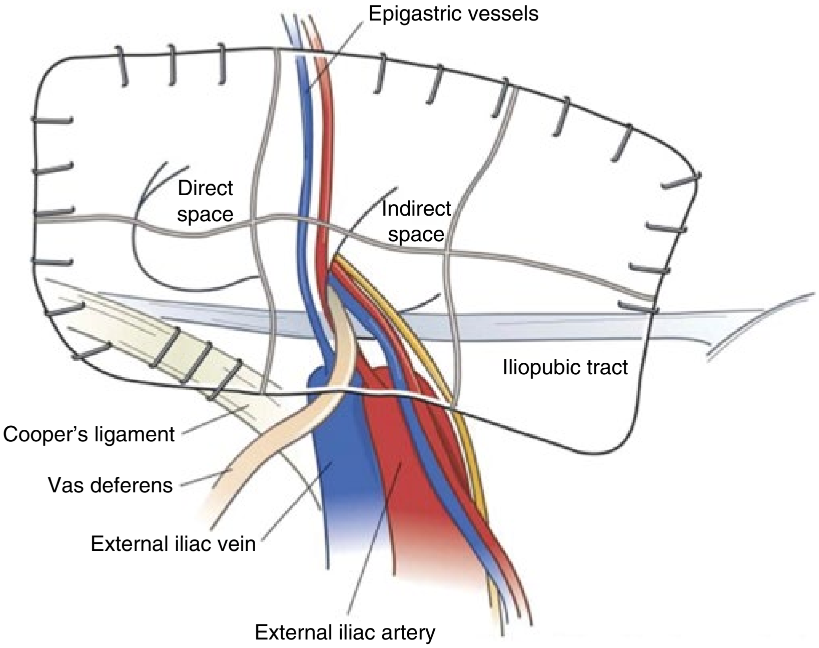

**Figure 113.15** Preperitoneal anatomy for total extraperitoneal (TEP) repair.

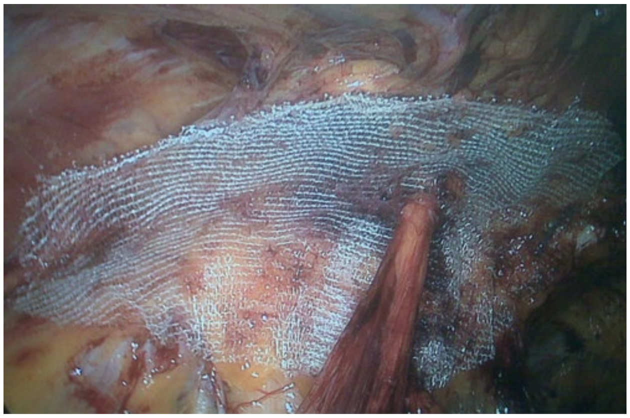

**Figure 113.16** Placement of mesh for total extraperitoneal (TEP) repair.

hernia can occur with 10 mm ports and rarely in 5 mm port sites. The use of cutting trocars with 10 mm fascial defects without closure are felt to be the primary cause of postop hernia. Many cases of Richter's type hernia in the trocar site can present with intestinal obstruction.

### Spermatic cord injury

Injuries to the testicular vessels leading to ischemic orchitis are well described in open inguinal hernia repair. These injuries occur much less frequently in the laparoscopic approach. Scrotal swelling and pain do occur as in open repairs and are related both to scrotal hematoma and irritation of the genital nerve. Hydrocele formation after laparoscopic repair is extremely rare and equals that found in open repair. Urinary retention also occurs with the same frequency as in open repair (2%).

Postoperative seroma and hematoma are relatively common in laparoscopic repair and most often resolve spontaneously. Regarding the use of mesh, infection after laparoscopic repair is extremely uncommon, as is erosion into surrounding structures. Infection and erosion of material requiring explantation and repair are rarely reported.

## Parastomal hernia

It is important for the endourologist to understand the causes and management of parastomal hernia. As with any iatrogenically created trephine, hernia complications are well described.

Parastomal hernia can lead to incarceration, poor fitting ostomy appliances with leakage, skin breakdown, and irritation (Figure 113.18). Parastomal hernias are reported to occur in as many as 50% of patients with a stoma [15] (Figure 113.19). Most often, these are elderly patients, considered high risk for surgical intervention who will end up living with a hernia without repair. In approximately 10–20% of patients, repair of parastomal hernia will become necessary secondary to symptoms of obstruction and poorly controlled stomal effluent. Of all surgically created ostomies, ileal conduit hernia carries an incidence of up to 6.5% [16]. Risk factors for the development of parastomal hernia are similar to those for incisional hernia. Elderly patients, high body mass index (BMI), respiratory comorbidity, cancer, and diabetes mellitus are all documented risk factors. Technical factors such as creating a small aperture size (less than 25 mm), stoma created through the rectus abdominis,

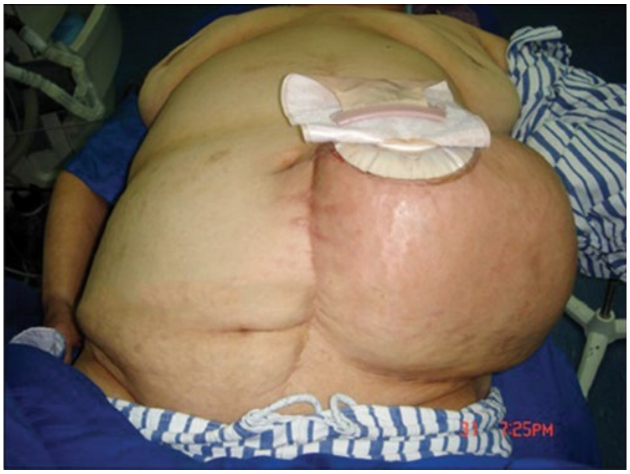

**Figure 113.18** Large parastomal hernia.

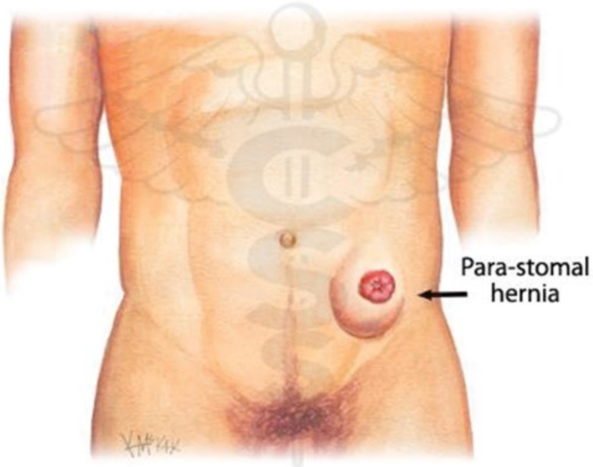

Para-stomal hernia

**Figure 113.19** Parastomal hernia.

and extraperitoneal stoma formation have all been studied and cited as important technical considerations. No randomized trials currently exist to evaluate these factors.

As stated, repair of parastomal hernia will only become necessary in a minority of patients. Symptoms of obstruction or incarceration are frequent indications for surgery, as is a poorly fitting ostomy appliance with chronic leakage. Initially, simple fascial closure of the defect around the existing stoma was used with poor results secondary to high rates of recurrence. This led to stoma relocation in which a laparotomy was necessary to close the existing defect and create a new stomal opening in the abdominal wall. Although still an alternative today, the magnitude of this approach carries higher attendant risk secondary to the laparotomy and potential for hernias at both the new and previous stoma sites.

As with incisional hernia repairs, the use of mesh in parastomal repair has gained acceptance. Both open and laparoscopic techniques are currently acceptable with mesh used to either bridge the defect or overlap the defect after closure. This can be accomplished as a mesh onlay or sublay with a keyhole cut around the bowel (Figure 113.20). Another technique, described by Sugarbaker, places mesh both around the defect and the stoma itself, with lateral egress of the bowel between the mesh and the abdominal wall at a distance of at least 5 cm from the stoma site [17] (Figure 113.21).

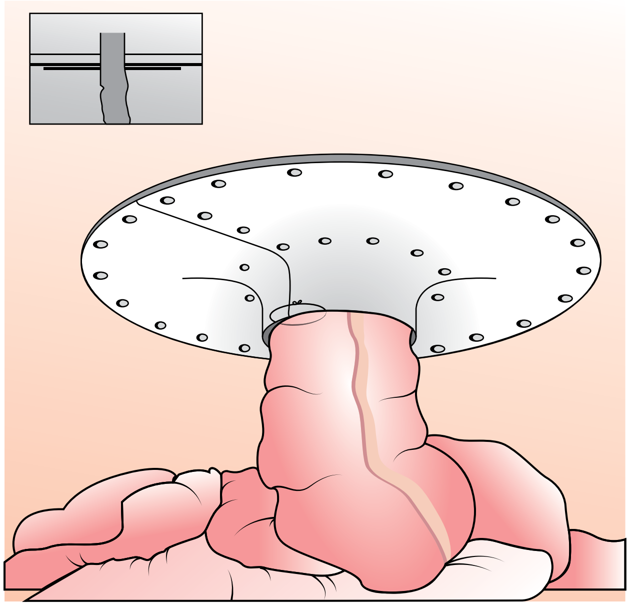

**Figure 113.20** Keyhole repair parastomal hernia.

Another technique, described by Berger and Bientzik, employs two layers of intraperitoneal mesh, one with a keyhole and a second to lateralize the stoma. The reported recurrence rate of this repair, initially performed in 47 patients, was 2.1% [18].

### Results

A meta-analysis by Hanson et al. in 2012 compared the results of parastomal hernia repair with respect to technique, mesh placement, keyhole, or Sugarbaker technique, and laparoscopic versus open repair. The analysis led to the following conclusions:

- Suture repair has a higher recurrence rate than mesh repair.
- Open and laparoscopic repair are comparable with equal rates of recurrence.
- The subgroup of laparoscopic repairs utilizing the Sugarbaker technique had a lower recurrence rate in the keyhole method [19].

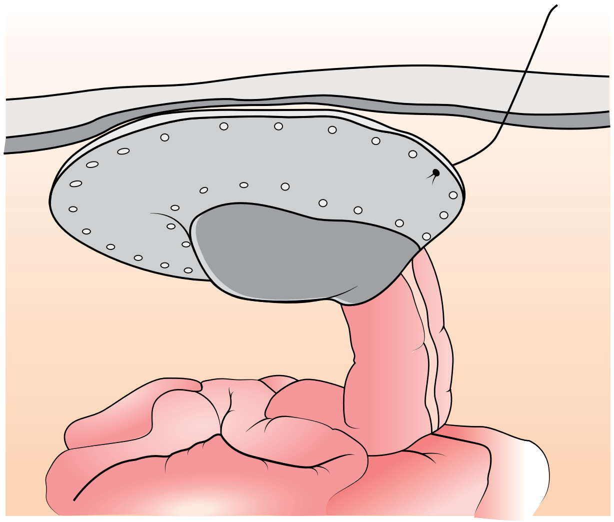

**Figure 113.21** Sugarbaker repair.

In more recent studies, the laparoscopic technique, as is true for other incisional hernias, shows a tendency towards shorter hospital stays and decreased surgical site infection [20]. Recent studies have also demonstrated that prophylactic mesh placed at the time of permanent stoma formation appears to decrease the incidence of parastomal hernia formation [21].

## Conclusions

A working knowledge of the current techniques employed in the repair of abdominal wall hernias is helpful for the practicing endourologist. With respect to technique, utilization of mesh prosthetics, and potential complications, any surgeon performing hernia repair should understand the potential outcomes and pitfalls. It should also be clear that a case can be made for either a laparoscopic or open approach depending on the clinical circumstances and experience of the operating surgeon.

# Robot-Assisted Vasectomy Reversal

*Parviz K. Kavoussi*

*Department of Reproductive Urology, Austin Fertility & Reproductive Medicine/Westlake IVF, Austin, TX, USA*

## Introduction

Approximately 500 000 men in the United States undergo vasectomy every year. With a divorce rate of approximately 50% in the United States, up to 6% of men who have undergone vasectomy will elect to have the vasectomy reversed some time in their lifetime [1, 2]. Vasectomy reversal (VR) was described in the 1930s and the use of the operative microscope for magnification to assist in the anastomosis was applied in the 1970s with significantly improved patency rates [3–5].

For years, people have been dreaming of robots. Whether it has been for science fiction or for practical uses, the idea of robots mechanically assisting us with tasks has seemed appealing. We used to hear people say "some day robots will do surgery for us." This has not necessarily become the case, but robots are finding more utility in assisting us with surgery. The da Vinci® system began with uses for gross surgical procedures and has expanded its utility to microsurgery. In urology, this particularly lends itself to VR. Surgery that we initially tried with the naked eye advanced through multiple technologies including optical loupes, operative microscopes, and now the operative robot. The advantages of using robotics to assist with microsurgery include the ability of devices such as EndoWrists® to work with seven degrees of freedom, enabling movements that the human hand and wrist cannot make, an ergonomic design for the surgeon which is less fatiguing and that may enhance performance, the scalability of motion, and high-definition 3D optimal visualization of a microsurgical field. Once the learning curve for robotic microsurgery is mastered by microsurgeons it should improve operative times as well.

## Anatomy

Understanding the anatomy of the vas deferens and the epididymis is paramount to a successful outcome with VR and the same is true for robot-assisted vasectomy reversal (RAVR). The vas deferens is a tubular structure derived embryologically from the mesonephric (Wolffian) duct. It extends from the distal end of the cauda of the epididymis and the tortuous segment leaving the epididymis for the first 2–3 cm is known as the convoluted vas deferens. The vas deferens measures between 30 and 35 cm in length from the cauda epididymis to the ejaculatory duct, where it terminates. It travels behind the vessels in the spermatic cord, posteriorly. Depending on the segment, the lumen of the vas deferens ranges between 0.2 and 0.7 mm in diameter [6]. The deferential artery, a branch of the superior vesical artery, supplies the vas deferens [7]. The venous drainage of the scrotal vas deferens is via the deferential vein, which drains into the pampiniform plexus. The venous drainage of the pelvic vas deferens is via the pelvic venous plexus. The lymphatic drainage travels to the external and internal iliac nodes.

Sperm travel through the epididymis from the testis to reach the vas deferens. If uncoiled, the tightly coiled tubular epididymis would stretch to 3.5–4.5 m long. The three regions of the epididymis are characterized as the caput (head), the corpus (body), and the cauda (tail). The caput epididymis comprises 8–12 ductuli efferentes from the testis. The most distal portion of the cauda epididymis is continuous with vas deferens. The arterial supply of the caput and corpus epididymis is from a branch of the testicular artery, which further divides to

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

Companion website: www.wiley.com/go/smith/textbookofendourology

supply the superior and inferior epididymal branches [8]. Branches from the deferential artery provide vascular supply to the cauda epididymis. Venous drainage of the corpus and cauda epididymis are via the vena marginalis of Haberer, draining into the pampiniform plexus via the vena marginalis of the testis, or through cremasteric or deferential veins [8]. Lymphatic drainage of the caput and corpus epididymis is through channels that travel with the internal spermatic vein, draining to the preaortic nodes. Lymphatic channels from the cauda epididymis join those leaving the vas deferens to drain into the external iliac nodes.

## Preoperative evaluation/physical examination

Prior to undergoing RAVR, the level of spermatogenesis in the patient should be assessed. A history of fertility from prior to the vasectomy is typically considered sufficient. A full physical examination should be performed prior to RAVR with special attention to the genital examination. Testicular volumes and consistency should be assessed. Firm, normal-volume testicles are indicators of good spermatogenesis, whereas small or soft testes may indicate some spermatogenic deficiency. It is not uncommon for the epididymis to feel dilated on examination in men who have undergone vasectomy. Epididymal induration may indicate the need for robot-assisted vasoepididymostomy (RAVE). When a large vasectomy defect or gap can be palpated, this should prompt counseling for a more extensive dissection to perform a tension-free anastomosis. When a sperm granuloma is palpated at the testicular end of the vas deferens, this indicates leaking of sperm as a result of a pop-off valve-like mechanism to decrease intraepididymal pressures. Sperm granuloma are associated with better outcomes with VRs, suggesting that the epididymis has protected itself by decreasing intraluminal pressures [9]. When physical examination reveals a very long vasectomy defect, a segment that has been removed, the surgeon should consider a nonstandard incision approach [10].

As more men are being diagnosed with hypogonadism and are being treated with testosterone replacement therapy, adversely impacting the level of spermatogenesis, medical management must be considered prior to performing RAVR in these men. Testosterone replacement should be discontinued, testicular salvage therapy with clomiphene citrate or human chorionic gonadotropin (hCG) should be implemented for approximately three months, and then RAVR can be performed with acceptable outcomes [11].

The obstructive interval since the vasectomy has a significant impact on the type of RAVR required, whether robot-assisted vasovasostomy (RAVV) or RAVE. This has been shown to affect patency rates in many studies on VR; in general, the longer the interval since vasectomy, the more challenging the candidate is considered to be for VR [12, 13]. However, in the hands of a surgeon who is proficient in both RAVV and RAVE, RAVR should still be offered to men with longer obstructive intervals. In technically skilled hands, success rates remain high regardless of the type of VR performed in men with obstructive intervals over 10 years [14].

Multiple nomograms have been constructed to predict the type of VR required and patency rates. Factors evaluated to assess these outcomes include patient age, testicular volume, the presence of sperm granuloma, and obstructive interval [15, 16]. There is a question over the accuracy of the nomograms and their utility with inconsistent data [17, 18]. As it is not typically possible to predict preoperatively if vasoepididymostomy will be required, VR should only be performed by surgeons skilled in both vasovasostomy and vasoepididymostomy [19, 20].

Before a man undergoes RAVR, his female partner should undergo a fertility evaluation, with counseling on female age and ovarian reserve impact on the couple's fertility potential [10].

## Preoperative laboratory testing

Semen analysis with a centrifuged evaluation of the pellet may be performed prior to VR. Ten percent of these centrifuged pellets will reveal whole sperm, suggesting good outcomes and indicating that sperm will be found in the vas deferens at least unilaterally at the time of VR [21]. When the semen analysis reveals low semen volume, transrectal ultrasound should be performed to rule out the possibility of a concomitant ejaculatory duct obstruction.

When the physical examination indicates potential spermatogenic deficiency with findings such as small, soft testicles, a serum follicle-stimulating hormone (FSH) should be obtained. An elevated FSH indicates spermatogenic failure, a potentially poor outcome with VR, and may be a predictor of the need for higher levels of assisted reproduction care [22]. Serum antisperm antibody (ASA) testing is not recommended as a routine preoperative test prior to VR. Approximately 60% of men develop circulating ASAs after bilateral vasectomy [23]. Preoperative ASA testing is of unproven value, and the high postoperative conception rate after VR questions the impact of circulating ASAs on fecundability [24–31].

## Anesthesia

RAVR may be performed with local, regional, or general anesthesia [10]. As meticulous robot-assisted microsurgical technique and tissue handling is mandated for superior outcomes, general anesthesia is the anesthesia of choice to minimize patient movement and to optimize patient comfort. Although RAVR can be performed with local anesthesia with sedation, this tends to result in more motion, which makes a challenging operation even more challenging. If a RAVE or a more difficult anastomosis is required, it may require lengthy operative times which can be difficult for the patient under local anesthesia or sedation.

## Patient positioning

The patient is placed in the supine position. After induction of general anesthesia, all pressure points are padded and the scrotum is shaved, prepared, and draped. Once the vasa are prepared and ready for the anastomosis, the operative robot is brought in from the patient's right side at a 90° angle with the 0° camera placed directly over the operative field of the scrotal incision, perpendicular to the floor (Figure 114.1).

## Incision approaches

The scrotal incision provides the most direct access to the vasectomy defect to isolate the ends of the vas deferens for anastomosis. In scenarios with high vasectomy defects or long vasectomy defects, the incision may be extended toward the external inguinal ring. The testis may be delivered in cases with a very low vasectomy defect or when a RAVE is deemed necessary. Mini-incision VR using no-scalpel vasectomy principles has been evaluated and found to have comparable patency rates with less postoperative pain and faster functional recovery [32, 33]. Mini-incision RAVR is the author's approach of choice, using an incision less than 1 cm.

In men who have previously undergone varicocele repair or inguinal hernia repair, the surgical approach to RAVR will vary. If a man has undergone varicocele repair for orchialgia or for hypogonadism with a concomitant vasectomy, the RAVR should be approached through the prior subinguinal incision after confirming that the vasectomy was performed subinguinally by previous operative report. In men who have suspected vas deferens obstruction from previous inguinal herniorrhaphy, approaching the RAVR through the previous scar will lead to the site of the vas deferens obstruction. RAVR following herniorrhaphy has also been performed intra-abdominally with robot assistance. This is a prime example of the robotic platform's ability to improve access to a difficult vas deferens repair [34, 35].

## Preparing the vas deferens

Once the vasectomy defect is isolated through the incision, the abdominal and testicular ends of the vasa may be isolated with the use of vessel loops. Care should

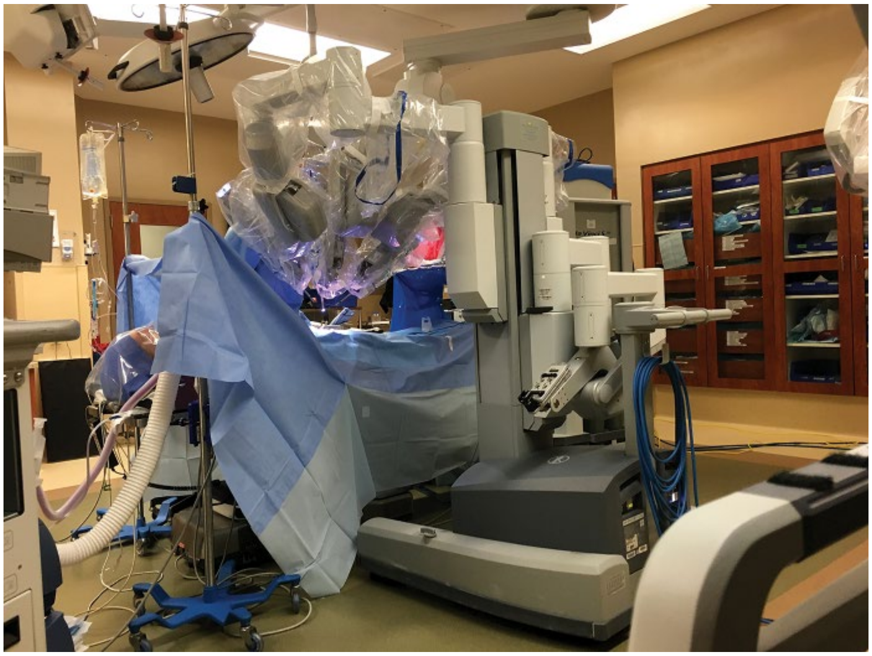

**Figure 114.1** The robotic system is positioned at a 90° angle to the patient with the camera positioned directly above the operative field (view from console).

be taken to not strip the vas deferens of the perivasal adventitia to maintain the microvasculature supply to the vas deferens. The abdominal and testicular ends of the vas deferens are adequately mobilized, with its adventitia intact, to allow for a tension-free anastomosis. The obstructed segment of the vas deferens at the vasectomy defect site may be excised or excluded. Care should be taken to preserve the deferential artery during this maneuver. After the testicular and abdominal ends of the vas deferens are isolated, the testicular end of the vas deferens is sharply divided at an exact 90°. The divided end of the vas deferens should have the muscularis and the mucosa inspected to confirm that there is a healthy surface to anastomose without fibrosis or scar.

Fluid from the testicular lumen of the vas deferens is then applied to a glass slide, diluted with a drop of saline, and examined under the light microscope (Figure 114.2). The quality of the fluid from the testicular end of the vas deferens and the microscopic findings dictate whether a RAVV or a RAVE should be performed. If microscopic examination of the vasal fluid reveals whole sperm with tails (Figure 114.3) or when there is copious, clear fluid from the vas deferens but no sperm are found in the fluid, RAVV should be performed. If fluid is not present, a 24 gauge angiocatheter sheath is cannulated into the lumen of the testicular end of the vas deferens and barbotage is performed with 0.1 ml of saline, which is then microscopically examined. If there is no significant vasal fluid or sperm identified after this maneuver, a RAVE should be performed. When the vasal fluid appears thick and toothpaste-like in quality, sperm are typically not found on microscopic examination of the fluid, and RAVE is indicated.

Over 90% of VRs will be successful when sperm fragments (sperm heads and/or short tails) are found in the vasal fluid intraoperatively, regardless of the fluid quality. This success rate surpasses the expected success rate with vasoepididymostomy [36, 37]. Sperm quality has been categorized in five grades to describe the findings in the vasal fluid. Grade 1 reveals mainly normal motile sperm, grade 2 mainly normal nonmotile sperm, grade 3 mainly sperm heads, grade 4 only sperm heads, and grade 5 no sperm [38, 39].

The abdominal end of the vas deferens is divided in a similar manner. The lumen is gently cannulated with a 24 gauge angiocatheter sheath and saline is injected into the lumen to demonstrate patency (Figure 114.4). Once abdominal vasal patency has been demonstrated, the ends of the testicular and abdominal vas deferens are approximated with the use of a Microspike approximating clamp, or with carefully placed 6-0 polypropylene adventitial sutures to approximate the ends with the help of an assistant. A Penrose drain covered metal ruler or tongue blade is then placed beneath the approximated

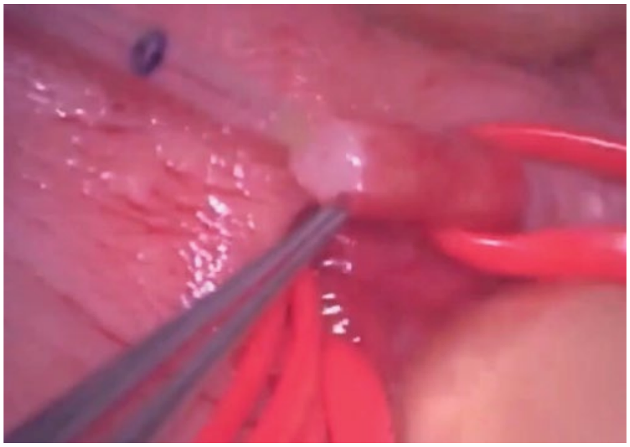

**Figure 114.2** Obtaining vasal fluid from the testicular end of the vas deferens to evaluate under the microscope.

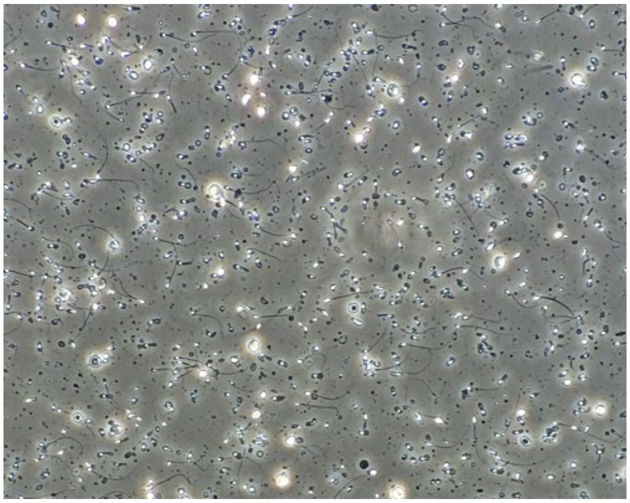

**Figure 114.3** Whole sperm visualized under the light microscope in the vasal fluid.

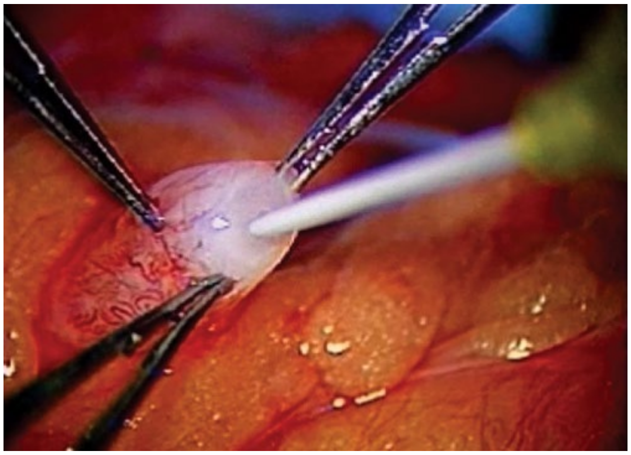

**Figure 114.4** Injection of saline through the abdominal end of the vas deferens to demonstrate downstream patency.

ends to provide a template for the anastomosis. If when saline is injected into the lumen of the abdominal end of the vas deferens the saline does not easily flow and there is high pressure, it suggests that there is no patency and that there is another obstruction further downstream in the abdominal end of the vas deferens. A 2-0 polypropylene suture is carefully passed through the lumen of the abdominal vas deferens to encounter the site of distal obstruction. If this obstruction is isolated within 5 cm of the initial vasectomy site, the abdominal end of the vas deferens may be dissected to the obstruction site and excised to perform one anastomosis after further mobilization of both ends to allow for a tension-free anastomosis. This may require extension of the incision. Performing multiple anastomoses on the vas deferens increases the risk of devascularization and failure.

## Anastomosis pearls

A high level of robotic microsurgical expertise is required for optimal RAVR outcomes. Prognostic advantages are gained by strict surgical principles during the anastomosis. The luminal mucosa of the abdominal and testicular ends of the vas deferens should be approximated meticulously. The anastomosis should be watertight as sperm are antigenic and will stimulate an inflammatory response which can lead to fibrosis and obstruction of the anastomosis if they leak at the anastomosis [40]. A tension-free anastomosis is crucial for long-term success. Mobilizing the abdominal and testicular ends of the vas deferens and placing reinforcing muscularis sutures to minimize tension on the anastomosis will improve long-term patency rates. A minimal touch technique, with as little manipulation as possible of the vasal ends for anastomosis is paramount to a successful outcome, as is maintaining microvascular supply to the vas deferens by maintaining the vasal adventitia and not stripping the vas deferens.

## Robot-assisted vasectomy reversal

VR has traditional been performed with magnification through the use of the operative microscope. Recently, da Vinci® robot assistance has been applied to VR. Robotic assistance was first utilized *ex vivo* on human vas deferens to perform RAVV, and it was found that it eliminated physiological tremor and gave comparable patency rates, suggesting that the operative robot may be used as an alternative to the operative microscope [41]. RAVV and RAVE were then performed in the rat model. The findings were improved stability and motion reduction during suturing of the anastomosis [42]. A multilayered RAVV was performed in an *in vivo* rabbit model with comparable patency rates, reinforcing the suggested role of robotics in microsurgery [43]. RAVR was performed in humans and resulted in shorter operative times and higher sperm counts in early postoperative semen analyses when compared to microsurgical VR [44]. A validating human study on RAVR compared to microsurgical VR demonstrated comparable patency rates, operative times, and early postoperative sperm concentrations and total motile counts. Although the mean anastomosis time in the RAVV group was statistically significantly longer in the early robotic experience than in the microsurgical group, this equated to a 10-minute longer mean anastomosis time clinically in the RAVR group [45].

The suggested advantages of the use of the operative robot for RAVR include: elimination of physiologic tremor, improved stability, surgeon ergonomics/decreased surgeon fatigue, scalability of motion, 3D high-definition visualization, the ability of the surgeon to manipulate three surgical instruments and the camera simultaneously, not requiring a specialty skilled microsurgical assistant, and the potential of improving operative times [45]. This early data show promise, but large-scale prospective, randomized controlled trials are needed to validate the broader adoption of robot assistance for VR.

The robotic platform provides advantages for more challenging scenarios such as intra-abdominal VR following laparoscopic vasectomy or in men with vasal obstruction due to inguinal hernia repair with mesh [34, 35].

## Robot-assisted microsurgical vasovasostomy

The same microsurgical tissue-handling principles that are used during microsurgical VR are applied to RAVR. The robotic microsurgical Black Diamond forceps are utilized in both the right and left robotic arms. The 0° camera is utilized and the 4× setting is selected. Scalability of motion is set at 3:1. RAVV may be performed by a modified one-layer anastomosis, placing 4–8 interrupted 9-0 Nylon sutures through the full thickness of each end of the vas deferens lumens (Figure 114.5). The same microsurgical principles of needle and suture handling that are used with microsurgical instruments should be applied to the robotic Black Diamond forceps in order to not bend needles or break sutures. Following the placement of these sutures, interrupted 9-0 Nylon sutures are placed between these full-thickness sutures in the muscular layer (Figure 114.6) [46]. Once completed, the anastomosis should be watertight and the vasal adventitia should be maintained to decrease the risk of stricture from microdevascularization (Figure 114.7).

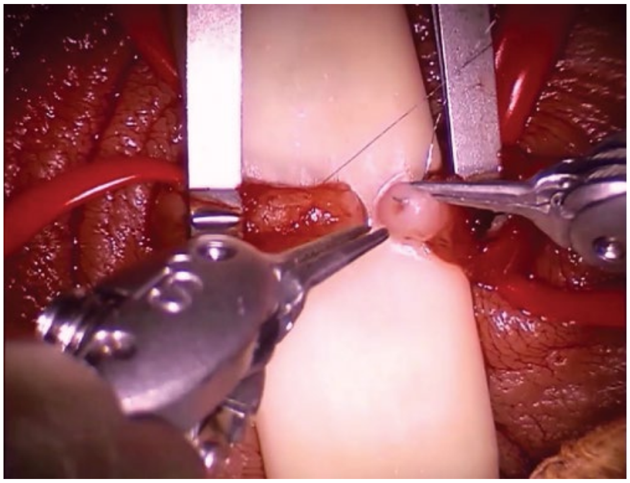

**Figure 114.5** Placement of a transluminal anastomotic suture with robot assistance.

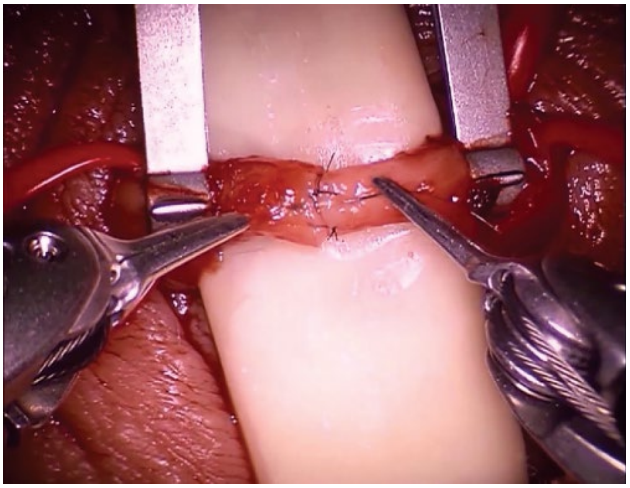

**Figure 114.6** Placement of interrupted suture in the seromuscular layer of the vas deferens between the transluminal anastomotic sutures with robot assistance.

Some surgeons prefer a two-layer anastomosis, which is performed by placing 5–8 10-0 Nylon interrupted sutures to approximate the inner mucosal edges of the ends of the vas deferens. Following the placement of these mucosal sutures, 7–10 outer muscular layer interrupted sutures of 9-0 Nylon are placed [39]. Experienced robotic microsurgeons compensate for the discrepancy in luminal diameters between the abdominal and testicular ends of the vas deferens during the anastomosis. Some place microdots with a microtip marking pen to preplan suture placement prior to performing the anastomosis [47]. This technique utilizes interrupted 10-0 monofilament Nylon sutures for mucosal approximation and interrupted 9-0 monofilament Nylon sutures deep in the muscularis in between the already placed mucosal sutures.

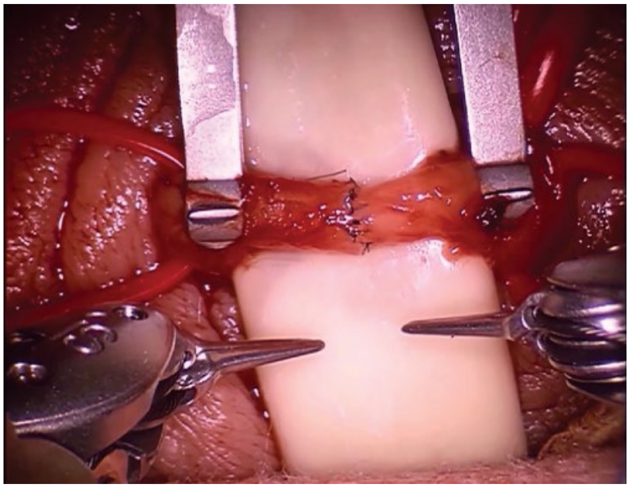

**Figure 114.7** The appearance of a watertight anastomosis with the vasal adventitia intact upon completion of a robot-assisted vasovasostomy.

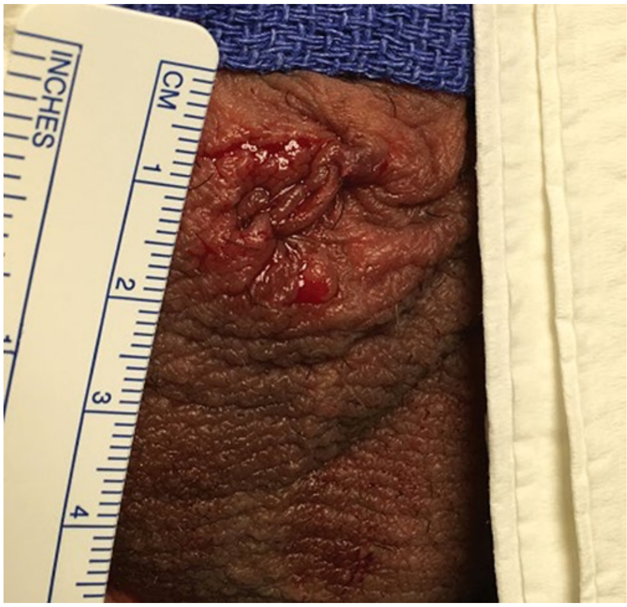

**Figure 114.8** Demonstration of a single <1 cm incision after closure following bilateral robot-assisted vasovasostomies.

When vasovasostomy is performed in the convoluted vas deferens, meticulous technique is mandated for a successful outcome. Although this anastomosis is more technically demanding, patency rates are comparable to anastomosis in the straight portion of the vas deferens when performed by skilled microsurgeons [48, 49]. The majority of RAVVs may be performed through one small incision, typically less than 1 cm in length, which assists with recovery and leaves a very small cosmetic incision with absorbable skin sutures (Figure 114.8).

A useful maneuver in difficult circumstances is the trans-scrotal crossed vasovasostomy. This technique allows for anastomosis of one testicular end of the vas deferens to the contralateral abdominal end of the vas deferens. It is used when there is unilateral inguinal vas deferens obstruction associated with an atrophic testis on the contralateral side, or obstruction of an inguinal vas deferens and epididymal obstruction on the contralateral side [1, 39, 50, 51]. Repeat VR is a valid option for men who failed an initial VR. The decision to perform a repeat VR should be based on the obstructive interval, the original VR, and the experience of the surgeon[52, 53].

When vasovasostomies are performed after sperm is found in the vasal fluid of at least one side, postoperative patency is demonstrated by the presence of sperm in the ejaculate in up to 99.5% of men [47]. One-layer vasovasostomy and two-layer vasovasostomy have been shown to have similar patency rates [54, 55]. Pregnancy rates within 2 years of VR of 52% have been achieved and up to 63% with exclusion of female factor and when based on female partner age and the time since vasectomy [9, 56–60]. Postoperative semen quality and female factors and age of the female partner determine the rates of spontaneous conception in couples after VR [54, 61].

## Robot-assisted microsurgical vasoepididymostomy

RAVE is a highly technically demanding operation and should only be performed by robotic microsurgeons with appropriate training and experience in this operation who perform it frequently. When the decision to perform a vasoepididymostomy is made, anastomoses are less technically challenging and more likely to succeed in the distal regions of the epididymis, as the epididymal wall thickens more distally with more smooth muscle cells. As the corpus and cauda of the epididymis is a single microscopic tubule, obstruction at any point will lead to a complete blockage of sperm from entering the vas deferens. The use of magnification significantly improves vasoepididymostomy patency rates [62, 63].

Multiple techniques have been employed to perform vasoepididymostomy. It may be performed by end-to-end or end-to-side anastomosis [19, 20], but the end-to-end anastomosis has fallen out of favor for the most part. The end-to-side vasoepididymostomy is performed by identifying the presence of markedly dilated epididymal tubules and approximating the muscularis and adventitia of the vas deferens to a specific opening in the tuinca of the epididymis. This is a relatively bloodless and atraumatic technique [20, 63–67]. The testis is delivered through a scrotal incision. The vas deferens is isolated with a vessel loop at the junction of the straight and convoluted vas deferens. The vas deferens is transected sharply and is prepared as previously described above. The tunica vaginalis is incised and the epididymis is inspected under magnification. The anastomotic site on the epididymis is identified where tubules are dilated, proximal to the suspected obstruction. A 3–4 mm incision is made in the tunica with the tip of the robotic micro-Potts scissors overlying the dilated tubules. The epididymal tubules are gently dissected and exposed.

The end of a 10-0 Nylon needle is used to puncture the selected epididymal tubule and the fluid is examined microscopically to identify sperm. The vas deferens is secured to the epididymal tunica with 3 or 4 interrupted 6-0 polypropylene sutures with positioning allowing the vasal lumen to reach the opening of the epididymal tunica without tension. Under high magnification, interrupted 10-0 monofilament Nylon sutures double armed with fishhook-tapered needles are used to approximate the posterior mucosal edge of the epididymal tubule to the posterior vasal mucosa. Two to four additional 10-0 sutures are used for the anterior mucosal anastomosis. Six to ten additional interrupted 9-0 sutures are used to approximate the outer muscularis and adventitia of the vas deferens to the incised edge of the epididymal tuinca. The robotic system is undocked and the testis and epididymis are carefully placed back in the tunica vaginalis and the scrotum is closed in layers.

The authors preferred technique for RAVE is the two-stitch intussusceptions technique. Two parallel needles of double-armed 10-0 Nylon sutures are placed in the dilated epididymal tubule longitudinally without pulling them through to avoid leakage of tubular fluid and collapse of the dilated tubule. The end of a 10-0 Nylon needle or the tips of the robotic microsurgical Potts scissors are used to make an opening longitudinally in the tubule between the parallel placed sutures. The fluid is examined microscopically for the presence of sperm. The needles of the pre-placed 10-0 Nylons are then passed inside out the vas deferens mucosa to perform the intussuscepted anastomosis (Figure 114.9) [63, 67–69]. The muscularis and adventitia are anchored to the epididymal tunica as described above.

In the hands of experienced, skilled microsurgeons, vasoepididymostomy patency rates are reported between 50% and 85% [68, 70]. Men who underwent the classic end-to-side or older, less commonly performed end-to-end anastomosis will have respective patency and pregnancy rates of approximately 70% and 43% [62, 71]. For the intussuscepted techniques, patency rates range between 70% and 90% [63, 67, 72].

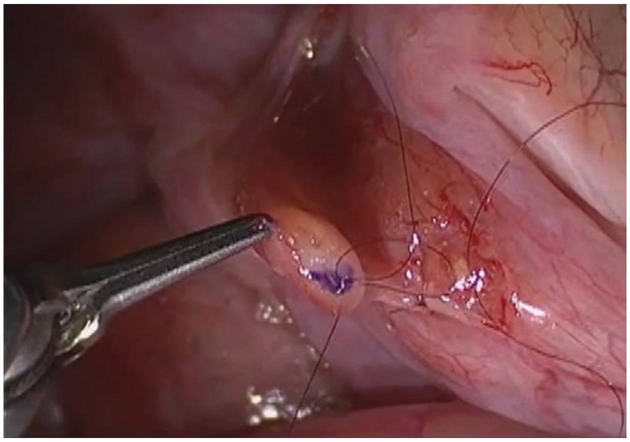

**Figure 114.9** Performing the anastomosis of a robot-assisted vasoepididymostomy with a two-suture intussuscepted technique.

## Postoperative care

Immediately following RAVR, the patient should be placed in a tight-fitting scrotal supporter with fluff gauze. Postoperative antibiotics are not indicated. Analgesics may be given. Most men return to work three days postoperatively as long as they do not partake in heavy or physical activity at work. No intercourse, ejaculation, exercise, or strenuous activity is allowed for three weeks after surgery. Semen analysis is obtained at six weeks, three months, and six months postoperatively and every six months thereafter until the couple achieves a pregnancy or further assistance is required. If azoospermia persists at six months postoperatively, this indicates a failure of the procedure.

## Complications

Hematoma and infection are rare complications of RAVR. Late stricture and obstruction are represented by progressive loss of sperm motility followed by decreasing sperm counts and eventually azoospermia in some men. Late obstruction has been reported to range between 5% and 12% at 18 months following VR [72, 73]. As a precaution, it is recommended that men cryopreserve sperm once motile sperm are identified in the ejaculate after RAVR as a safety backup.

# Part 6 Laparoscopy/Robotics in Children

## 115

## Laparoscopic Considerations in Children

*Rajeev Chaudhry,*[1] *Michelle Yu,*[2] *& Michael C. Ost*[1,2]

### Introduction

Laparoscopy in pediatric urology began in 1976, when Cortesi et al. reported diagnostic laparoscopy to evaluate nonpalpable testes [1]. Since then, laparoscopy in children has gained widespread popularity. It has become a safe and effective approach for several different pediatric urologic procedures.

In 1991, Bloom introduced laparoscopic ligation of testicular vessels for first-stage Fowler–Stephens [2]. A year later, Jordan and Winslow described the first laparoscopic orchiopexy [3]. Work by these early pioneers led to diagnostic laparoscopy becoming the gold standard approach to evaluating nonpalpable testes. More importantly, laparoscopic orchiopexy, whether single or staged, has become an advantageous approach to treating high intra-abdominal testes [4, 5].

In its infancy, laparoscopy was adopted slowly by pediatric urologists. The instruments were cumbersome and limited, making the procedures technically challenging laparoscopically, while open surgery had very high success rates. Today, with the advancements of minimally invasive tools for pediatric patients, new technology, and increase in surgeon experience, laparoscopy has found a niche in pediatric urology as a safe, effective, and well-established alternative to many pediatric urologic procedures beyond orchiopexy, including nephrectomy, partial nephrectomy, pyeloplasty, hernia repair, varicocelectomy, bladder reconstruction, and antireflux surgery [6, 7]. The first pediatric laparoscopic nephrectomy was described by Koyle et al. in 1993 [8].

In July 2000, the US Food and Drug Administration approved the use of the da Vinci™ Surgical System (Intuitive Surgical Inc., Sunnyvale, CA, USA). Robotic surgery has now replaced several of these laparoscopic procedures, but laparoscopy still has a role to play.

### Safety and efficacy

Initial criticism towards laparoscopy included the longer operative times and high success rates with open procedures through small incisions that obviated the need for a minimally invasive approach. In the hands of skilled surgeons, the benefits of pediatric laparoscopy are similar to those in adults: it offers decreased incisional pain, shorter recovery times, and enhanced cosmesis [9, 10].

Complications rates are relatively low. Laparoscopic orchiopexy is still the most common laparoscopic procedure performed by pediatric urologists, and success rates are as high as 90% with complications rates less than 3.0% [11]. Peters reported a complication rate of 5.4% in 5400 pediatric urologic laparoscopic cases. This number decreased to 1.2% once preperitoneal insufflation was excluded. This same study found that surgeon experience was the strongest predictor of complication rates [12]. In a recent systematic review, Kim et al. reported a complication rate of 3.5% in transperitoneal laparoscopic renal surgery [13]. In a prospective study by Penn et al., laparoscopic pyeloplasty was found to be a safe and effective alternative to open approach, providing shorter hospital stays and similar postoperative outcomes [14].

### Indications

As mentioned above, laparoscopy has become the gold standard for evaluating nonpalpable testes. It provides a quick assessment of intra-abdominal space through a small incision at the umbilicus (Figure 115.1). If an intra-abdominal testis is discovered, the size and location

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

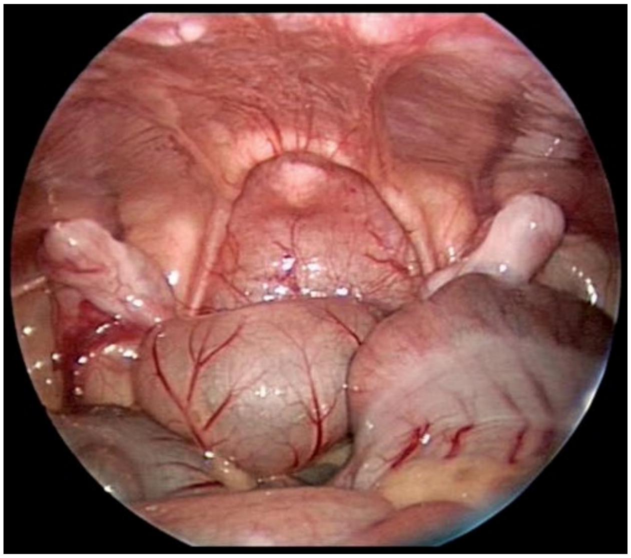

**Figure 115.1** Diagnostic laparoscopy aids in locating the position of intra-abdominal testicle. Depending on its position, the decision can be made to perform a single or staged laparoscopic orchiopexy, or an open inguinal orchiopexy.

are noted and the decision to proceed with laparoscopic single or staged orchiopexy can be made. If blind-ending vessels are noted in the rare case of vanishing testes, then no further action is needed and the patient spared an extrainguinal incision for exploration [4, 15].

Laparoscopic nephrectomy is usually indicated for removal of nonfunctioning kidneys secondary to obstruction, ureteral ectopia, or vesicoureteral reflux. The approach can be transperitoneal or retroperitoneal, with the former affording lower complication rates [13]. Laparoscopic nephroureterectomy and partial nephrectomy is performed to remove upper or lower pole moieties that are obstructed and nonfunctioning. Many authors argue that visualization of the renal vessels and moieties in a duplex system is much clearer laparoscopically than in open, helping to decrease the potential risk of vascular injury [15].

Laparoscopic pyeloplasty was first introduced by Peters in 1995 for treatment of ureteropelvic junction obstruction [16]. The procedure is technically challenging, but has good surgical outcome in high-volume centers [14]. This procedure has been replaced by a robot-assisted approach, but at several institutions around the world where robotics are unavailable, laparoscopic pyeloplasties are still being performed.

Other uses for laparoscopy include ureteral reimplantation, ligation of spermatic vessels for varicoceles, and reconstructive cases. Laparoscopic continence antegrade enemas and appendicovesicostomies have high success rates, decreased postoperative wound issues, and shorter convalescence times than the more morbid open procedures. Laparoscopic approach allows access to both upper and lower parts of the abdomen without having to make a large midline incision [17, 18].

## Anatomical and physiologic considerations

When considering a minimally invasive approach in children, one must be cognizant of the anatomic and physiologic differences between pediatric and adult populations. Pneumoperitoneum can produce significant changes to cardiac, respiratory, and autonomic physiology that must be recognized by both surgeons and anesthesia team.

Pneumoperitoneum can decrease ventricular preload, and although in children with normal cardiac function the changes are well compensated and the effects are negligible, in patients with congenital heart defects the result can be deleterious [19]. Moreover, abdominal distention can spark increased vagal tone and subsequent bradycardia, which can further decrease cardiac output in patients with cardiac insufficiency [20]. Temporary desufflation and reinsufflation at lower intra-abdominal pressures may be necessary. Patients with known cardiac issues will need preoperative consultation with cardiology and even cardiac anesthesia at the time of surgery.

In children, chest wall compliance is increased while functional reserve capacity (FRC) is decreased. Pneumoperitoneum can cause increases in mean airway pressure and end-tidal $CO_2$, which further decreases FRC and lowers oxygen saturation [19]. Hypercapnia can also result due to the increased absorption of insufflated $CO_2$ gas across the peritoneum into the bloodstream. With these changes, alterations to minute ventilation may be required to restore normal end-tidal $CO_2$ levels. It is imperative for the anesthesia team to be aware of these slight physiologic changes and to make the appropriate adjustments in a rapid, timely fashion [21].

Increase intra-abdominal pressure in children reduces urine output, but this effect is transient and does not result in permanent renal damage [22]. Temperature regulation is another concern in the pediatric population. Children lose heat more rapidly than adults because of their greater ratio of surface area to body mass, and appropriate warming devices and temperature monitoring should be utilized by anesthesia throughout the case [23].

Abdominal wall compliance is increased in children, but the intraperitoneal space is comparatively small. Lower insufflation pressures at 4–12 mmHg (vs. 15 mmHg in adults) and decreased gas flow rates 1–3 l/min (vs. 40 l/min in adults) are necessary to avoid overdistention of the intra-abdominal cavity and severe physiologic changes. The pliability of the abdominal wall helps to maintain lower intra-abdominal pressures while achieving adequate insufflation volumes in an otherwise small cavity, allowing sufficient intra-abdominal working space for surgeons.

Given that the cavity is small, visceral organs and major vessels are in close proximity to one another, increasing the risk of injury upon initial entry into the abdomen. The pediatric abdominal wall requires less force for entry but is extremely pliable and thus once must take extreme caution when placing trocars (Figure 115.2a,b). The smaller abdominal area in the pediatric patient also means care must be taken when placing ports to ensure there is enough distance between the ports so that there is freedom of movement.

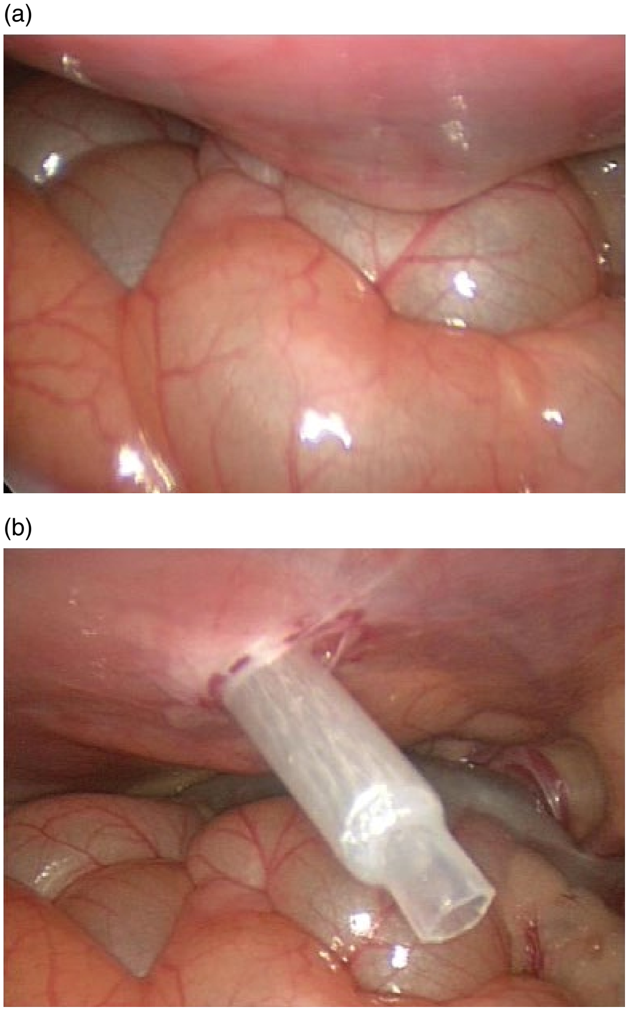

**Figure 115.2** (a) Note the abdominal wall compliance during entry of the port. (b) Placement of the step trocar.

## Instrumentation

The development of pediatric size-appropriate trocars and instruments has allowed laparoscopy to be more feasible and safer in the hands of experienced surgeon. Access is obtained using a Veress needle technique or an open technique. The Veress needle is a spring-loaded needle and punctures through the abdominal wall and then retracts once in the cavity to prevent visceral injury. Insufflation of the abdomen occurs though the Veress needle and then the initial trocar placement is performed blindly through the distended abdominal wall. Open techniques include box-stitch technique, Hasson cannula system, or radially dilating trocar, all of which involve an incision through fascia and ports placed while directly visualizing the viscera below. Direct open access through the umbilicus at its urachal attachment has gained popularity.

Pediatric trocars are smaller in diameter and shorter than their adult counterparts. Trocar diameters range from 3 mm to 5 mm in size. The 3 mm and 4 mm ports are metal and reusable, whereas the 5 mm ports are disposable and a step system can be used to prevent accidental dislodging of the port when removing instruments from the cannula. The camera port is usually 5 mm to accommodate the laparoscope. Instruments vary from 3 mm to 5 mm in size to accommodate the respective ports and are also shorter in length.

Endoscopic staplers now come in pediatric sizes that range from 2.5 mm to 12 mm to accommodate any size trocar that is being used. Pediatric LigaSure™ devices, electrocautery instruments, and clip appliers are also available. One must be careful with use of monopolar cautery as the tips get hot and may cause injury to nearby structures with direct contact. Moreover, because it is so small, the intra-abdominal cavity can overheat with excessive use of cautery.

## General complications

Laparoscopy introduces its own set of complications, including failure of instruments, camera failure, or problems with the insufflation. Complications can extend operative time, in particular time under anesthesia, which is especially important in the pediatric patient. Surgeons, nurses, and scrub technicians should be trained to troubleshoot these problems intraoperatively.

At the start of the case, patients are positioned and padded securely to prevent shifting or positional related injuries. During certain laparoscopic renal cases, patients are positioned in modified flank positioning, which

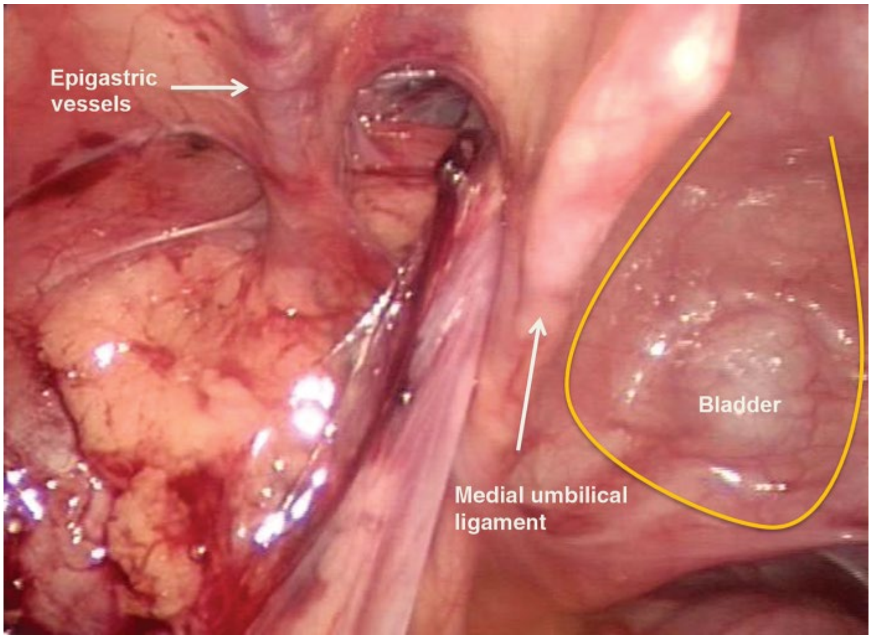

**Figure 115.3** Bladder injury during creation of neohiatus for a laparoscopic orchiopexy is of great concern given the close anatomic location to areas of interest during this procedure.

places stress on certain dependent portions of the body. Proper positioning is an important step to reduce neuromuscular injuries and decrease the chance of rhabdomyolysis. This step should not be ignored.

Complications in pediatric laparoscopic urologic surgery are similar to those in the adult: access or trocar injury, bleeding, hypercapnia, instrument failure, gas embolism, bowel or bladder injury, and thermal injury. In the literature, most complications do not require conversion to open. Esposito et al. reported a 0.85% conversion rate to open to repair complications [24]. Due to the smaller anteroposterior diameter of the pediatric patient, care must be taken in particular during access and trocar placement as previously mentioned. Open peritoneal access has been associated with lower complication rates than with Veress needle, with a 0.4% reported rate of epigastric and iliac vessel injury, and 0.1% rate of small bowel injury [25]. Bowel injury is a concern during laparoscopy during trocar placement, instrument passage, and use of cautery. Small injuries can be repaired laparoscopically, but larger injuries may require laparotomy and possible intraoperative consultation with a pediatric general surgeon.

Port-site herniation is a rare complication in pediatric population, but has been reported. Omental and bowel herniation rates have been reported 0.15%. Typically, 5 mm ports are left open in adults, but the fascia should be closed in children to prevent this complication [12, 26]. In contrast, 3 mm port sites are not typically closed, but there has been a reported omental herniation [27].

Bladder injury can be seen in laparoscopic orchiopexy and typically occurs at the time of neohiatus creation, with instrument passage to/from the scrotum (Figure 115.3). Reported rates in the literature are 0.03–0.17% [12, 28]. Steps to reduce risk of bladder injury include placing a urethral catheter during the case to empty the bladder, and adequate knowledge of pelvic anatomy and landmarks during creation of the neohiatus [28].

## Conclusion

This chapter covers a multitude of urologic applications of laparoscopy in children with high success rates and low complications. Surgeons and anesthesia teams alike need to understand the physiologic changes that occur in pediatric patients with pneumoperitoneum. With time and experience, surgeons have learned how to combat the challenges that laparoscopy presents intraoperatively. Good surgical technique, awareness of differences in the anatomy and physiology of the pediatric patient, and respect of the working space can help minimize complications overall. As the technology continues to evolve, laparoscopic instrumentation will become safer and easier to use, providing the surgeon with an an armamentarium of tools to perfect his or her laparoscopic technique.

# Laparoscopic and Robotic Pyeloplasty in Children

*Kai-wen Chuang*

*Department of Urology, University of California, Irvine, CA, USA*

## Introduction

Traditionally, open pyeloplasty (OP) has been the gold standard for treating ureteropelvic junction (UPJ) obstruction in children, with a success rate of 97% in the reported literature. However, with continued advances in conventional laparoscopic and robotic surgical technology, as well as a general shift in patients' and families' mentality towards favoring minimally invasive interventions, these approaches play a growing role in pediatric pyeloplasty. In the past, conventional laparoscopic pyeloplasty (C-LP) has been demonstrated to be equivalent to open surgeries in terms of preservation of differential renal function [1]. The technical challenges in C-LP largely lies in the need for intracorporeal suturing, which has been subsequently rectified by improved dexterity offered by robot-assisted laparoscopic pyeloplasty (RA-LP). The superiority of the laparoscopic approach over the open approach, with or without robotic assistance, is believed to lie in its decreased morbidities in terms of length of stay and pain medication requirement [2, 3]. This chapter reviews the strategies, techniques, and outcomes of laparoscopic and robotic pyeloplasty in children, as well as providing literature updates from the past 10 years, given that there has been a dramatic increase in relevant studies since the last edition of this chapter was published in 2012.

## Background

In 1993, laparoscopic pyeloplasty was first described in adult patients concurrently by two groups [4, 5]. Two years later, in 1995, its pediatric application was first described by Peters et al. in a 7-year-old boy with right UPJ obstruction, using the classic Anderson–Hynes dismembered technique, interrupted sutures, a nephrostomy tube as drainage, and 5 hours of total operative time [6]. More than a decade later in 2007, Olsen et al. reported their favorable 5-year experience with robot-assisted retroperitoneoscopic pyeloplasty (RA-RP) in treating UPJ obstruction in 67 children, demonstrating shorter operative times and comparable complication rates compared to other approaches.

Minimally invasive surgery has unique benefits in the pediatric population with respect to cosmetic outcomes, as well as psychological and social impact on the caregivers. It has been demonstrated that up to 83% of parents believe the scar size for pyeloplasty is important [7], and a validated questionnaire showed higher parental satisfaction rates for RA-LP over OP with regard to size of the incision scar, burden of postoperative follow-up, and overall life [8]. In addition, shorter length of stay (LOS) associated with RA-LP was correlated to an average saving of US$90.01 in parental wage loss and US$612.80 in hospital expenses [9].

However, these financial considerations must be weighed against the cost of purchasing and maintaining a robotic platform and instruments. Although Liu et al. did not find any differences in overall costs between minimally invasive pyeloplasty and OP, Bennett et al. reported that robotic cases were more expensive by US$3991, with operating room charges and anesthesia charges dominating the cost difference [10, 11]. Some centers have been successful in overcoming the higher costs associated with RA-LP by high surgical volumes, as Sorensen et al. observed that operative times for RA-LP were initially longer than those for OP, but became equivalent after 15–20 cases [12]. Having a dedicated robotic team in the operating team also improves efficiency and minimizes cost while maximizing safety.

With RA-LP rapidly showing signs of becoming the new gold standard for treating UPJ obstruction in children, it cannot be stressed enough that ultimately the decision-making regarding which surgical approach to take should be based on availability of equipment, family preference, and surgeon skillset and comfort.

## Indications

The indications for minimally invasive pyeloplasty are identical to those for OP, and include decreasing split renal function, increasing hydronephrosis, urinary tract infections or pyelonephritis, symptoms such as intermittent flank pain, nausea, or vomiting, and presence of nephrolithiasis [13].

There have been encouraging reports of expanding the application of RA-LP to include younger children and infants. The largest series of such nature was a multicenter retrospective review from Avery et al., examining the outcomes of 60 infants with a mean age of 7.3 months. It found 91% of the children with improved or resolved hydronephrosis, while 3.3% (2 patients) required reoperation due to recurrent obstruction [14]. Boysen and Gundeti detailed their suggestions for successful infant pyeloplasty from a technical standpoint, including positioning, port placement, lens degrees, and insufflation pressure [15].

However, overall, infant RA-LP remains in its early stages and it is standard practice at our institution to perform infant pyeloplasty cases via an open dorsal lumbotomy or flank approach. Interestingly, a recent crowd-sourced survey showed that the majority of patients would prefer the dorsal lumbotomy scar over flank and laparoscopic incisions, if given as an option [16]. We reserve minimally invasive pyeloplasty for older children and teenagers, with RA-LP being our first choice, and rarely C-LP if operating at an affiliated hospital without the robotic equipment.

## Patient preparation and operative setup

Here we describe the steps for a routine RA-LP performed at our institution. The steps for a routine C-LP are identical.

### Bowel preparation

Although some authors advocate for a liquid diet for 24 hours prior to laparoscopic surgeries and a single rectal suppository of oral bowel stimulant to clear the colon, we have not found routine preoperative bowel preparation to be necessary.

### Retrograde pyelogram and stent placement

As indicated above, our standard approach for infant pyeloplasty is via an open dorsal lumbotomy incision. As such, we routinely perform a preoperative retrograde pyelogram to assess possible kidney rotation, concomitant ureteral obstruction, and length of ureteral narrowing. Narayanan et al. reported that preoperative retrograde pyelogram can provide additional information in up to 19% of cases [17]. Following this practice, we also perform a routine retrograde pyelogram before our minimally invasive pyeloplasty cases.

However, there is variation among our partners regarding stent placement. For some, an internalized double-J ureteral stent is always placed in a retrograde fashion at the end of the retrograde pyelogram. They cite confirmation of distal curl in bladder by direct cystoscopic vision and not having to negotiate the ureterovesical junction (UVJ) blindly as major advantages over an antegrade stent placement approach. In this case, the bladder would be left full by clamping the urethral Foley catheter so that the renal pelvis can remain distended to facilitate dissection.

For others, an antegrade stent placement approach is preferred due to the added difficulty in intracorporeal suturing by the proximal curl of the stent interfering with visualization of the surgical field. This is the preferred approach by this author and will be discussed in more details in later sections. A Foley catheter is placed per urethra at the end of the retrograde pyelogram.

### Positioning

The patient is placed in the lateral decubitus position with the operative side up and rotated approximately 30° from the vertical plane. This position is maintained with one or two large gel rolls behind the patient. In order to maximize the movement range for the robotic arms, it is beneficial to have the front side of the patient as close to the edge of the operating room table as possible. Sequential compression devices are placed on bilateral lower extremities. The bottom leg is bent while the upper leg is straight, with a pillow in between them. The contralateral arm is extended and secured to a padded arm board, while the ipsilateral arm is folded across the chest. Care is taken to ensure that all bony prominences are well padded and protected. The patient is then secured to the table using folded blue towels and silk tape at three levels, across the chest, across the hip, and across the legs. The security of strapping is then tested by rolling the patient prior to draping. It is important to work closely with the anesthesia team, as the head may also need to be secured. An orogastric tube is placed for left-sided procedures. The patient is prepped over the entire abdomen from xyphoid to pubis.

### Access and port placement

For patients without prior abdominal surgeries, entry into the peritoneum is obtained via a Veress needle after making an incision at the base of the umbilicus with an 11 blade. Countertension is provided by a pair of symmetrically placed perforating towel clamps. For patients with history of prior abdominal surgeries, an open Hasson technique is the preferred method, given its inherent safety. Successful entry is confirmed by a satisfactory "saline drop" test, no bloody or bilious return on aspiration, and symmetric, four-quadrant insufflation with low starting pressure. Typically, a 5 mm port is first placed through the self-dilating sheath at the umbilicus and a 0° or 30° laparoscope is used through this port to facilitate placements of the two 8 mm robotic ports under vision, one cranial to the umbilical port in the midline and a second equidistant from the umbilical port in a caudal direction approximately 30° off the midline. Care is taken to ensure that there is at least a 6–8 cm distance between ports to maximize robotic arm movements. An additional 5 mm assistant port can be placed as needed to allow for passing of sutures, suctioning, and/or liver retraction for right-sided cases. At this point, the laparoscope is switched to one of the working ports looking back at the umbilicus, and the previously placed temporary 5 mm port is then upsized to a 12 mm robotic camera port under vision.

## Procedure in detail

Following port placement, the robot is docked, and the procedure begins with identifying the dilated renal pelvis. For dissection, this author prefers monopolar scissors in the right hand and bipolar grasping forceps in the left. For left-sided cases, a transmesenteric approach is preferred if possible. Otherwise, a retrocolic approach would be appropriate if a dilated pelvis is not readily visible through the colonic mesentery. The colon is mobilized by incision of the white line of Toldt and reflected medially. The hepatic flexure and the duodenum may need to be mobilized for right-sided cases, and the splenic flexure may need to be mobilized for left-sided cases in order to reveal the UPJ.

After the UPJ is successfully identified, dissection is carried out carefully while maintaining the ureteral blood supply. In our experience, a hitch stitch with 3-0 Prolene is very useful at this time to permit lifting, exposure, and stabilization of the UPJ and proximal ureter. This is placed percutaneously through the abdominal wall using either a straight Keith needle or a straightened needle through the renal pelvis and back through the abdominal wall. Tension can be adjusted by placing a pair of clamps on the extracorporeal ends of the suture at different levels. This maneuver also lefts the anastomotic area away from any potential pools of urine and blood.

The next step is to perform a pyelotomy. The cut into the pelvis is in a diamond shape, similar to OP. Posteriorly, the cut should be as close to the ureter as possible without cutting into it, as this would create a dependent lower vertex of the pelvis that will be sewn to the inferior aspect of the ureteral spatulation. The portion of the lower pelvis and the actual UPJ is now attached to the ureter and can be used as a handle for manipulation, in an effort to minimizing touching the anastomotic site. The ureters is spatulated laterally, away from the vascular supply, until the normal ureter is encountered. Again, preoperative retrograde pyelogram can provide added information regarding the length of the diseased segment.

The anastomosis begins at the inferior aspect of the spatulation and the inferior-most aspect of the renal pelvis using a 5-0 Vicryl suture cut to 12 cm in a running fashion. The posterior wall is usually closed first. After the back wall is completed, an antegrade stent is placed. This is accomplished by passing a 14-gauge angiocatheter through the abdominal wall and passing a guidewire with preloaded stent through the angiocatheter. The length of the stent selected is based on the formula (age in years + 10) or premeasured during retrograde pyelogram. The guidewire is advanced down the ureter as the stent follows behind. Proper positioning of the stent is confirmed by tactile feedback, as there should not be any resistance. Further confirmation that the distal end of the stent has reached the bladder can be obtained by filling the bladder, instilling blue dye in the bladder, clamping the Foley catheter, and observing reflux of blue urine through the stent. Following stent placement, the opposite wall of the anastomosis is completed using a second suture, also in a running fashion.

The decision whether or not to leave a wound drain is at the discretion of the operating surgeon. In this author's experience, a rounded Blake drain is preferred over a flat Jackson–Pratt drain or a Penrose drain because this still allows closure of fascial defect in excess of the drain without making drain removal difficult, thereby decreases the risk of port-site hernia.

The fascia at the umbilicus is typically closed with 2-0 Vicryl suture on an UR-6 needle in an interrupted fashion, while the fascia at the working port sites is closed using 3-0 Vicryl sutures.

## Application in variant renal anatomy

Although we have not had much experience in employing minimally invasive techniques in treating UPJ obstruction in pediatric patients with renal anomalies, success has been reported in pelvic kidneys as well as horseshoe kidneys [18–22].

## Other minimally invasive surgical techniques

A review of the literature demonstrated some novel adaptations to the standard surgical steps described in details above. Regarding access, laparoendoscopic single-site (LESS), as well as transumbilical multiport pyeloplasty cases have been reported before with outcomes comparable to those of C-LP in terms of success rates and complication rates [23–25].

Regarding port placement, Hong et al. reported that their hidden incision endoscopic surgery (HIdES) port placement for pediatric robotic pyeloplasty has outcomes comparable to those of traditional port placement in terms of operative times, narcotic administration, hospital stay, success rate, and complication rates [26]. In this innovative approach, the robotic camera port, a working port, and a 5 mm assistant port are placed below the line of a Pfannenstiel incision, while the second working port is placed at the umbilicus or infra-umbilically, thereby avoiding visible scars.

With regard to surgical steps,a vascular hitch procedure has been applied in pediatric pyeloplasty [27, 28] in cases of crossing vessels. In this approach, the aberrant vessel is wrapped in a sling of pelvic tissue which keeps the vessel above the UPJ. This shortens the procedure by avoiding dismemberment and suturing. However, many groups caution against this approach because the presence of a crossing vessel does not always rule out other concomitant intrinsic abnormalities of the ureter, such as polyps, stenosis, kinking, or high insertion.

In the non-dismembered category of surgical technique, a Heineke–Mikulicz repair has also been described, where the lateral aspect of the UPJ is incised longitudinally and then closed transversely [29].

## Postoperative follow-up

This author does not place children on routine prophylactic antibiotic after minimally invasive pyeloplasty, and this is in keeping with existing literature. In 2016, Ferroni et al. showed that the administration of extended prophylactic antibiotics after minimally invasive pyeloplasty with ureteral stent placement in children had no significant impact on the rate of urinary tract infection [30]. We typically obtain our first postoperative renal and bladder ultrasound about 4–6 weeks after the surgery while the stent is still in place. We find this study helpful in establishing the patient's new baseline renal appearance when drainage is maximized, which in turn assists with meaningful interpretation of stable but persistent hydronephrosis on subsequent ultrasound. If hydronephrosis is noticeably improved on this initial postoperative ultrasound, then the stent is removed via cystoscopy in the operating room. The second postoperative ultrasound is typically 6–8 weeks following stent removal, with the third ultrasound being another three months afterwards. In the event of consistently worsening hydronephrosis or persistent symptoms following pyeloplasty, a postoperative nuclear medicine renal scan is obtained to reassess the drainage pattern on the operative side.

## Complications

A review of the literature revealed that the rates for complications following a pediatric pyeloplasty is 10–15% overall, but only 2–3% if complication is defined as a need for repeat invasive intervention, comparable to Clavien III grading for adults.

### Persistent obstruction

This is considered the most significant complication of pyeloplasty and can be caused by edema or blood clot acutely in the perioperative period, or by stenosis or kinking of the repair more chronically. As stated in previous sections, consistently worsening hydronephrosis or persistent symptoms following pyeloplasty warrant evaluation for possible persistent or recurrent obstruction by way of a diuretic renogram. Alternatively, the patient can be taken back to the operating room 4–6 months after the initial procedure for retrograde pyelogram. At our institution, we typically attempt balloon dilation and double stent placement as the first-line intervention if a stricture is found on retrograde pyelogram. Post-balloon dilation follow-up timeline is similar to what was described earlier for initial pyeloplasty, with reoperative pyeloplasty as the next step should the endoscopic treatment fail.

### Urinary leak

If a wound drain is left in place at the end of the pyeloplasty, sometimes persistent urinary drainage can be present postoperatively. In this situation, maximal urinary drainage is of value. Ureteral stent or nephrostomy tube placement should be considered if the initial pyeloplasty was done without a stent. Occasionally, postoperative urinary retention can contribute to urine leak from the anastomosis due to backflow through the stent. In this situation, Foley catheter replacement is the next step, and it is usually left in place for 3–5 days. Repeat voiding trial can occur when narcotic is minimized and bowel regimen is optimized.

### Complications related to laparoscopy

Similar to other laparoscopic procedures, C-LP and RA-LP carry the risks of access-related complications, such as bowel injury, adjacent organ injury, port-site hernia, and port-site infection, as well as insufflation-related complications, such as hypercarbia, increased abdominal pressure affecting ventilation, and hypothermia. With improved optics and visibility during laparoscopy, the incidence of these complications is low. However, children do have higher risk of severe injury, owing to their size and physical characteristics [31].

## Comparative outcomes

Since the last version of this chapter was published in 2012, there have been many more studies systematically examining the success rates and complication rates of pyeloplasty in children using different surgical approaches. In 2015, Ekin et al. wrote a review paper providing an up-to-date overview of minimally invasive treatment methods in UPJ obstruction [32]. In 2017, Boysen and Gundeti reviewed the technique, outcomes, complications, and special considerations in infants with respect to RA-LP in the pediatric population [15]. The author summarizes the overall findings in the following sections and refers interested readers back to these two review articles for details of individual studies regarding publishing year, number of cases, and study design.

### Descriptive series

A review of pediatric C-LP case series revealed that average operative time ranges from 140 to 255 minutes, with follow-up period from 13 to 41 months and a success rate of 91–100% [32]. A similar review of pediatric RA-LP case series revealed that average operative time ranges from 105 to 198 minutes, with follow-up period from 12 to 31 months and a success rate of 94–97% [15].

### Conventional laparoscopic versus open pyeloplasty

In 2017 in a comparative, prospective, case–control study of C-LP versus OP in children with UPJ obstruction, Piaggio et al. found that C-LP was a longer procedure than OP, but that both procedures had the same efficacy and complication rates. Patients who underwent C-LP needed fewer narcotics and had a shorter hospital stay [33]. Also in 2017, Gatti et al. conducted a randomized, prospective, and controlled trial comparing C-LP versus OP in children. Their study demonstrated the same results of longer operative time and shorter hospital stay in the C-LP group [3].

### Robot-assisted laparoscopic versus open pyeloplasty

From 2006 to 2014, there were at least five comparative studies looking at the differences between RA-LP and OP. Overall, RA-LP takes longer than OP, but the difference starts to diminish after 20 cases and may not exist after 40 cases. RA-LP, when compared to OP, tends to have shorter LOS and decreased narcotic requirement.

### Conventional versus robot-assisted laparoscopic pyeloplasty

When comparing the two minimally invasive approaches, C-LP and RA-LP, RA-LP tends to have shorter operative time and no difference in LOS or narcotic requirement. However, in the study with the most patients, Silay et al. reported in 2016 that operative time was similar between RA-LP and C-LP [34]. This study presented results from the Pediatric Urology Expert Group of the European Association of Urology Young Academic Urologists, which may explain their proficiency in conventional laparoscopic suturing and may not necessarily be applicable to an average urologist without advanced conventional laparoscopic skills. In this group of practitioners, the dexterity and three-dimensional visualization offered by robotic assistance can conceivably be beneficial and may level the playing field.

### Three-way comparison between open, conventional laparoscopic, and robot-assisted laparoscopic pyeloplasty

In 2017, Song et al. retrospectively reviewed an age-matched cohort of 30 children who underwent OP, 30 who underwent laparoscopic-assisted extracorporeal pyeloplasty, and RA-LP [35]. They found that those who underwent RA-LP had a shorter LOS and decreased narcotic requirement; however, there was no difference in the success rates for OP, C-LP with extracorporeal suturing, and RA-LP. Interestingly, the presence of crossing vessel was a negative prognostic indicator for surgical outcomes regardless of surgical method.

Also in 2017, Chan et al. aimed to determine if surgical approach, age, case volume, or other factors influence perioperative outcomes of pediatric pyeloplasty at academic institutions in a large contemporary cohort of 2219 patients. They found the complication rates to be 2.1%, 2.2%, and 3% after OP, C-LP, and RA-LP, respectively [36]. This large multicenter analysis also demonstrated that patient comorbidity had the greatest impact on complication rates and LOS.

## Reoperative pyeloplasty

Indications for reoperative pyeloplasty are similar to those for initial pyeloplasty, and include decreased renal function, worsening hydronephrosis, and persistent symptoms. As mentioned in previous sections, retrograde pyelogram, balloon dilation, and double stent placement is usually the first-line intervention at our institution for those who show signs and symptoms of failed initial pyeloplasty for UPJ obstruction. Should the endoscopic intervention fail as well, then typically the surgical approach for reoperative pyeloplasty is open at our institution.

However, minimally invasive approaches have been described and studied in the pediatric population in the context of reoperative pyeloplasty. In 2017, Moscardi et al. compared their outcomes of reoperative C-LP to primary C-LP and found similar results regarding safety and effectiveness [37]. Transperitoneal laparoscopic approach following a failed open pyeloplasty has the benefits of entering a virginal surgical territory and avoiding scar tissue, as most likely the OP would have been done via a retroperitoneal approach [29].

## Conclusions

Traditionally, pediatric patients with UPJ obstruction are treated with open pyeloplasty. However, with the advancement in laparoscopic and robotic surgical technology, a minimally invasive surgical approach, particularly with robotic assistance, is rapidly becoming the new gold standard worldwide for this procedure in children. Since the last version of this chapter was published in 2012, there has been a raft of newer studies with improved follow-up, continuing to demonstrate that the safety and effectiveness of these approaches is comparable to the open approach. The benefits are also possibly extended to younger patients and even infants [36].

In conclusion, the author wishes to remind the readers that when interpreting outcome results it is important to clarify each study's definition of success and complication and to not automatically equate statistical significance with clinical significance. To have a successful RA-LP series, having a dedicated robotic operating room staff and appropriate mentoring are extremely important [38]. Ultimately, the approach to UPJ repair should be based on availability of equipment, family preference, and surgeon skillset and comfort, rather than classically objective outcomes measures.

# Lower Ureteral Reconstruction: Robotic Surgery

*S. Duke Herrell*

*Vanderbilt University Medical Center, Nashville, TN, USA*

## Introduction

Obstruction of the lower ureter requiring reconstruction can take place from a variety of extrinsic and intrinsic causes, including both non-iatrogenic and iatrogenically induced strictures. In addition, diseases such as reflux and other bladder-related issues, such as diverticuli, might necessitate ureteral reimplantation. The treatment paradigm for distal ureteral obstruction evaluation and treatment should be well known to most practicing urologic surgeons. The evaluation of distal ureteral obstruction is often focused at attempting to delineate the causal events. Workup and evaluation of the various differential diagnoses are beyond the focus of this chapter.

Urologic surgeons may bring varied skills, including endourologic, laparoscopic, robotic, and open surgery, to bear on the complexities of distal ureteral obstruction. A standard underlying tenet of care is the appreciation and relief of complete or marked obstruction to prevent significant ongoing renal nephron functional loss. This may involve the use of temporizing endourologic and radiologic interventions such as ureteral stent placement or percutaneous nephrostomy tubes to relieve obstruction. Especially in cases where significant obstruction exists or there is evidence of longstanding hydronephrosis and parenchymal loss, the urologic surgeon should also employ selected radiologic studies such as computed tomography (CT) and nuclear scans to evaluate the overall functional status of the kidney prior to undertaking reconstructive surgery. In cases where the kidney is of minimal function, typically less than 15% with a normal contralateral kidney, nephrectomy should be considered in appropriate patients if symptoms or complications such as pain, infection, hematuria, or significant renal-based hypertension are found and necessitate intervention.

Specific cases such as bladder tumors causing local invasion and obstruction of the ureter as well as distal ureteral tumors are beyond the scope of this chapter and are managed according to standards of oncologic practice. In certain distal ureteral tumor scenarios, utilization of reconstructive efforts described in this chapter, such as either psoas hitch or Boari flap, follow the standard approach as noted below when oncologically appropriate [1, 2]. Techniques differ from benign stricture disease as the distal ureter is usually completely removed and surgeons are encouraged to utilize caution in the approach to distal ureteral tumors as implantation of tumor remains a risk for this often aggressive disease.

This chapter describes the robotic and laparoscopic options for managing common distal ureteral obstruction scenarios. Readers are encouraged to review other sources as to the etiology, diagnosis, and indications for management in specific disease processes. This chapter will concentrate on surgical technique for laparoscopic and robotic approaches to distal ureteral reconstruction.

## Diagnostic evaluation

The evaluation of distal ureteral stricture disease, especially if no causative factors are apparent, should include the process of ruling out the presence of intrinsic or extrinsic malignancy. Distal ureteral stricture disease is often related to stone disease. Although endoscopic treatments for stone disease have advanced, the presence of long duration impacted stones as well as iatrogenic damage to the ureter can still cause ureteral stricture. Additional causes of benign ureteral strictures are numerous and include pelvic radiation for a variety of malignant pelvic disease processes, infection, endometriosis,

trauma, and inflammatory disease, such as retroperitoneal fibrosis and pelvic lipomatosis.

Modern diagnostic studies typically include CT urogram as well as potentially retrograde or antegrade pyelography combined with endoscopic evaluation performed prior to definitive intervention. At the time of this endoscopic evaluation, the status of the bladder, especially in patients who have neurogenic bladder or other potential complicating factors such as radiation to the pelvis, should be assessed as to the bladder tissue's potential suitability as a ureteral substitute if necessary. In some selected scenarios, endoscopic intervention such as endoureterotomy can be employed for short strictures to avoid ureteral reimplantation or reconstruction. Endoscopic incision is typically only successful for strictures less than 2 cm without underlying tissue compromise by radiation. Use of endoureterotomy via both antegrade and retrograde approaches is discussed in other chapters within this text.

Some contraindications to procedures such as psoas hitch and/or a flap include the presence of significant bladder outlet obstruction, neurogenic dysfunction, or significant reduction in bladder capacity or tissue mobility. In these circumstances consideration of other repair methods such as ileal interposition, autotransplantation, or even urinary diversion may be warranted.

## Basics of surgical repair

A variety of techniques are available to reconstruct distal ureteral obstruction. Urologic surgeons should be familiar with each of these techniques and their potential use as well as indications and contraindications in different patterns of ureteral length loss. In most surgical situations the intrinsic involvement of the ureter has been assessed prior to surgical intervention with radiologic and endoscopic evaluation. The general tenets of open surgery that have existed for decades underlie the choice made for reconstructive efforts in distal ureteral obstruction and have been emulated in modern robotic and laparoscopic procedures. Preoperative assessment will often give clues to the length of ureter involved with the stricture process that will need to be bridged in some manner to reach the bladder or perform a primary anastomosis. Historically, most disease processes involving the distal ureter have been defined as the pelvic brim to the bladder. Most "distal" strictures have been approached with reimplantation of the ureter directly into the bladder via either mobilization of the bladder (psoas hitch) for use of a flap of bladder tissue (Boari flap) [3–5]. In rare cases, primary ureteroureterostomy might be feasible but is typically more employed for the upper or mid ureter. Lower ureteral stricture repair is best managed by reimplantation into the bladder when feasible.

The length of ureter involved by stricture and damage differentiates the various surgical techniques. Urologic surgeons should be knowledgeable about the typical length gained by employing these maneuvers. Surgical maneuvers and techniques such as ureteroureterostomy (length of ureteral involvement is 2–3 cm), ureteroneocystostomy (length 4–5 cm), psoas hitch (length 6–10 cm), and Boari flap (length 12–15 cm) are often employed. Typically, for distal strictures, reimplantation into the bladder is the preferred management paradigm. Additional techniques such as renal mobilization with nephropexy (renal descent) can provide an additional 5–8 cm of ureteral length, but this is typically mainly useful for mid-ureteral and upper ureteral strictures [6]. In certain cases renal mobilization with nephropexy can aid in the performance of an especially long Boari flap type repair. Additional procedures that can be employed for even more significant ureteral length loss such as transureteroureterostomy, ileal ureter, buccal ureteral graft, and autotransplantation are available and reviewed in multiple publications throughout the urologic literature [7, 8]. There has been some literature experience with performing these procedures with laparoscopic or robotic approaches but these have been relatively limited in number and experience to date [9–12].

## General concepts

### Surgical scenarios

In many of the surgical scenarios, the precise type of repair to be employed will not be completely understood until a full dissection of the surrounding structures and identification of the length of ureter involved with stricture and damage which needs bypassed or replaced is understood. Unfortunately at times the ureter may be more involved than originally anticipated. One of the key tenets of ureteral repair surgery is that, similar to urethral repair, diseased tissue is removed until good, viable, full-thickness tissue with blood supply is encountered. Even if this involves conversion to a more extensive repair procedure the success rate is highest when tissues with excellent blood supply make up both sides of the anastomosis site. Informed consent should be obtained for all potential procedures, including psoas hitch, Boari flap, ureteral replacement, and even possible autotransplantation. Certainly for extensive or long strictures the patient should be aware of the potential to need a larger or more complex procedure.

### Patient preparation

A patient's preparation is performed depending on the clinical scenario and follows the typical evaluation for major urologic surgery. We typically employ a mild preoperative bowel prep to aid with bowel decompression. In patients with history of extensive previous transabdominal surgery consideration should be given to full bowel prep if the potential of enterotomy is high and depending on institutional standards. In addition, if the stricture is long and the potential exists for ileal interposition, a more complete bowel preparation may be considered. Standard preoperative preparation is performed as per institutional and physician protocol.

### Preoperative presence of drains and tubes

In our practice, we typically remove the ureteral stent 4–6 weeks prior to the proposed repair if one is indwelling. If it is a more complete obstruction or the patient has significant obstructive pain then a percutaneous nephrostomy tube is placed ipsilateral. In our experience the ability to differentiate healthy ureteral tissue is enhanced by the removal of an indwelling stent several weeks prior to the proposed procedure, similar to the removal of transurethral catheters prior to urethroplasty surgery.

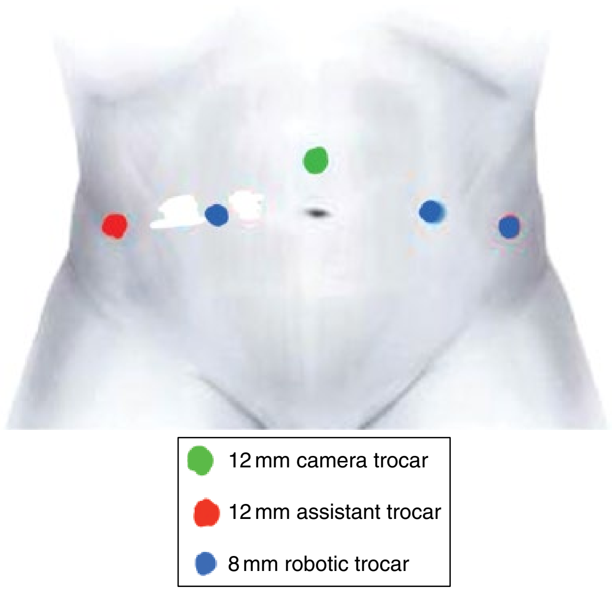

**Figure 117.1** The trocar arrangement is standard for pelvic surgery. The camera is docked through a 12 mm supra-umbilical midline port. We typically place the robotic fourth arm to the contralateral side from the strictured ureter to allow for use in providing traction on the bladder. For longer, more proximal strictures, such as those requiring extensive Boari flaps, the trocars can be moved cephalad.

## Intraoperative

### Position and preparation

Patient positioning for the majority of distal ureteral surgeries has the patient placed in a standard low lithotomy supine position similar to standard robotic pelvic surgery. Standard preparation for laparoscopic-based surgery includes an orogastic tube and a Foley catheter, which is placed transurethrally sterilely onto the field. In addition, if a nephrostomy tube is present we typically connect this to tubing extenders so that injection and irrigation are possible.

In some cases the complexity of the previous abdominal surgeries, operative field, or situation may necessitate the urologist perform a cystoscopy and place a retrograde ureteral stent and wire to aid in finding the ureter. This is possible only if the ureter is patent distally. For the majority of repairs, this is not necessary. In specialized procedures for distal ureteral tumors, the urologist may wish to perform cystoscopy to ensure that the bladder is free of any tumor or extensive progression of the distal ureteral tumor, depending on the oncologic scenario

### Entry and port placement

For both robotic and laparoscopic repairs, standard abdominal entry techniques and port placement geometry are employed. We currently perform the majority of these repairs robotically as it aids in suturing, especially for complex flap repairs etc. Although we have had extensive experience in performing these with pure laparoscopic techniques in the decade prior, there is no doubt in our opinion that the suturing, while feasible laparoscopically, is made easier to both perform and learn with the robot.

We typically employ all four arms of the robot. The fourth arm can be placed either ipsilateral or contralateral depending on surgeon preference. A 12 mm assistant port is placed opposite the fourth arm. Standard port configuration for pelvic surgery is employed, although typically the trocars are moved more cephalad (2–5 cm superior to the umbilicus), especially for more extensive flap type repairs (Figure 117.1). With the newer da Vinci™ Si and Xi platforms (Intuitive Surgical Inc., Sunnyvale, CA, USA) the ability to extensively move quadrants within the abdomen aids in performance of these procedures. Especially in reoperative or iatrogenically caused injuries, surgeons may be required to perform extensive adhesiolysis to gain exposure to the pelvis, ureter, bladder, and the site of injury. In some scenarios mobilization of the kidney may be necessary, making patient positioning and repositioning more complex. Conversion to open surgery may be required. All surgeons undertaking these types of reconstructive efforts should be well versed in laparoscopic, robotic, adhesiolysis, and versatile repair techniques.

## Basic surgical techniques

In most scenarios discussed in this chapter, the surgeon will enter with the plan of either performing a direct ureteroneocystostomy for short, very distal injury, a psoas hitch for a slightly longer distal injury, or a Boari flap combined with a psoas hitch in more severe and lengthy distal strictures. As stated previously, the surgeon should be prepared to perform more advanced procedures such as transureteroureterostomy, ileal ureter, or autotransplantation for extensive ureteral disease processes or loss and if the clinical situation requires.

Ureteral exposure is the initial step after any adhesiolysis. The surgeon should identify the ureter superior to the involved obstructed segment. We typically mobilize the ipsilateral colon superior to the external and common iliac vessels along the white line of Toldt. The fourth arm or the assistant can aid in retraction of the colon to allow dissection to proceed into the retroperitoneum. Mobilization of the colon superiorly and inferiorly along the white line of Toldt aids in full exposure. The surgeon should typically attempt to get the ureter at a level that is uninvolved superior to the disease process at this point. For the majority of repairs this will involve identifying the iliac vasculature and the ureter superior to or as it courses over the iliacs. During this dissection the surgeon should remain cautious of the gonadal vessels and, if feasible, preservation of these with lateralization is performed. In some scenarios the disease process does not allow preservation of the gonadal vessels and they should be hemostatically secured and divided only when absolutely necessary. We typically get circumferentially around the ureter superior to the iliac vessels once we have dissected and lateralized the gonadal vasculature. We often employ a vessel loop or Penrose drain to encircle the ureter for retraction, especially if it is involved in a severe amount of scar tissue or disease process as it approaches the iliac level. Using the fourth arm for assistance to gently retract the ureter superiorly using the vessel loop allows the surgeon to dissected caudally toward and over the iliacs (Figure 117.2). At this point the ureter should be dissected down circumferentially to the level where marked involvement in the obstructive disease process is noted. For benign processes the ureter can then be divided just superior to its involved segment. In malignant intrinsic ureteral tumors the dissection is carried completely to the bladder as per standard oncologic principles.

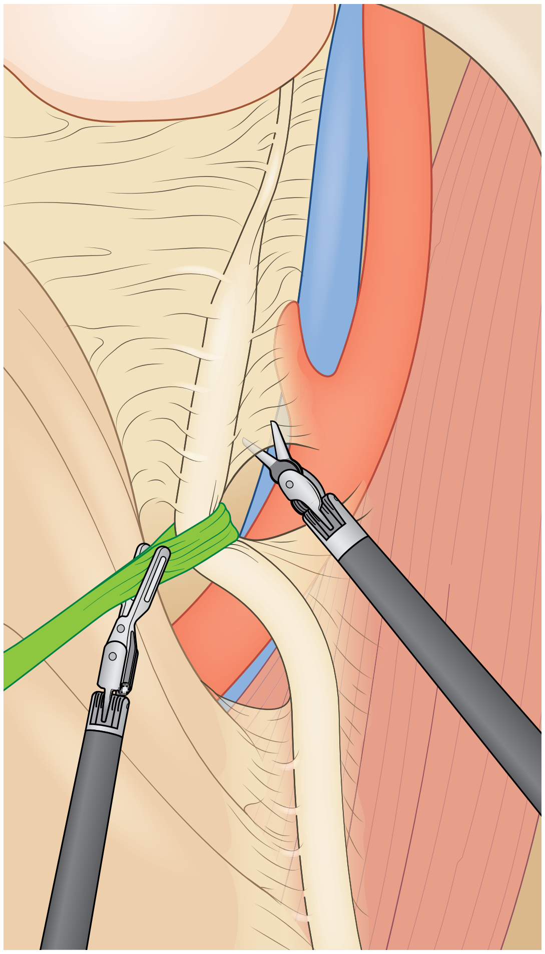

**Figure 117.2** The obstructed ureter is exposed and dissected superiorly about the external iliac vessels, with care taken to preserve adventitial blood supply. Once it is circumferentially dissected at a normal level, a vessel loop can be passed around it and the robotic grasper used to provide retraction as the surgeon works with either scissors or cautery to dissect caudally toward the stricture level and the bladder.

Once the ureter is divided, we typically remove our vessel loop or Penrose drain at this point and place a stay suture at the very distal end of the ureter as we prepare for the next steps of the operation. Although the ureter is typically spatulated later in the procedure, we typically avoid spatulation at this point until we have conceptualized how the repair will proceed in terms of eventual reimplantation. This decision impacts the orientation of the spatulation, which is typically anterior (hitch or flap) but can be posterior for a direct onlay dome reimplant (ureteroneocystotomy) such as a modified Lich–Gregoir. Handling of the delicate ureter especially at the level of where the eventual anastomosis will be performed is discouraged. Care is taken to preserve maximal vascularity and adventitia around the ureter during the exposure and dissection. Surgeons should avoid “stripping” the ureter, as this will often remove vital adventitia and blood supply, placing the distal ureter at risk for stenosis. During this dissection a cephalad portion of the ureter is typically mobilized which will avoid tension during the subsequent anastomosis.

At this point the various repair types diverge as to technique, depending on the necessity to make up longer distances of ureteral loss or removal. Each type of repair will be covered separately with technical nuances in the subsequent text of this chapter.

## Ureteroneocystotomy

Once the more caudal end of the ureter has been identified and the stricture level defined during full dissection the surgeon can appreciate the length of ureter which must bridge with the bladder. In some circumstances, when the ureter is strictured quite distally, mobilization of the bladder is not needed. In these scenarios a direct reimplantation onto the dome or posterior bladder can be performed. If a direct dome reimplantation is possible, techniques such as the direct onlay reimplantation where the ureter is spatulated posteriorly and directly anastomosed with a refluxing anastomosis onto the bladder dome is performed. Surgical standards include the performance of a direct mucosa-to-mucosa anastomosis with absorbable suture. In most circumstances an interrupted technique is employed, using 4-0 or 5-0 suture of either Vicryl or PDS. Care is taken to minimize manipulation and grasping of the distal ureter, especially the mucosa. Options to aid manipulation include a traction suture, leaving a small piece of strictured ureter attached to the distal ureter for grasping and mobility (subsequently excised), placing a segment of small ureteral catheter in the end of the ureter and grasping the catheter, or simply only grasping the seromuscular tissue cautiously. In the case of an ureteroneocystotomy, the bladder is incised with cautery through the seromuscular layers and then the incision in the mucosa is typically made with cold scissors. The incision should be approximately 1–2 cm.

The spatulated ureter and bladder are anastamosed with interrupted sutures of fine absorbable suture, typically 4-0 or 5-0 Vicryl or PDS, with care taken to get adequate mucosa and seromuscular tissue in each suture of each structure. We have observed some authors everting the mucosa of the bladder with fine absorbable sutures and then performing the mucosa-to-mucosa anastomosis. We also place a suture from the seromuscular layer of the bladder to the seromuscular layer of the ureter slightly away from the site of anastomosis to take any tension off during the anastomotic procedure. Prior to full closure of the anastomosis, a stent is placed into the ureter with the distal coil in the bladder. Stent placement techniques are discussed in a separate section later. Once anastomosis is complete, any residual vesicostomy is closed with running or interrupted suture. The bladder is irrigated to ensure a watertight closure. A standard closure of appropriate trocar sites along with a perivesical drain placement is performed. We typically leave the drain for 1–2 days or until minimal output and the Foley for 10–14 days. The Foley is removed at the time of clinic visit with a cystogram to ensure bladder closure, especially in cases of radiated or abnormal tissue healing potential.

## Psoas hitch and Boari flap

### Bladder mobilization

For both psoas hitch and Boari flap techniques, full mobilization of the bladder, including potential transection of the contralateral vesicle pedicle, can be performed to reduce tension on the anastomosis and allow for reconstruction tissue length from the bladder. Typically, we begin the process by filling the bladder with 150–200 ml of sterile fluid through the preplaced Foley catheter. We then mobilize the bladder from its anterior peritoneal attachments, similar to prostatectomy etc. In some cases with large bladders and psoas hitch approaches this is all of the mobilization needed, as the bladder's compliance and elasticity allow it to be pulled over to the ipsilateral psoas area for hitching. In other cases, a more thorough mobilization is necessary. This may even include division of the contralateral vesicle vascular pedicle to allow for full mobilization. During this mobilization, the posterior peritoneum is incised and the contralateral ureter should be identified thoroughly to ensure that there is no risk of damage to it during this pedicle mobilization process. A variety of technologies can be used to transect the pedicle contralaterally, including hemostatic vessel sealing, clips, or vascular staplers. Again, the urologic surgeon is cautioned to identify and prevent any damage to the contralateral ureter during this mobilization.

### Psoas hitch

For the standard psoas hitch procedure, the psoas minor tendon and fascia investing the iliopsoas is exposed superior to the common and external iliac artery. The bladder is grasped on its seromuscular surface and brought over to the iliopsoas where it is secured with 1–2 sutures that encompass the posterior seromuscular wall of the bladder without mucosa and the fascia investing the psoas. Often the psoas minor tendon can serve as a strong anchor point. Sutures are thrown through the psoas fascia and psoas minor tendon in a direction parallel to the muscle fibers to hopefully avoid nerve entrapment. Care is taken to only take superficial bites of the psoas

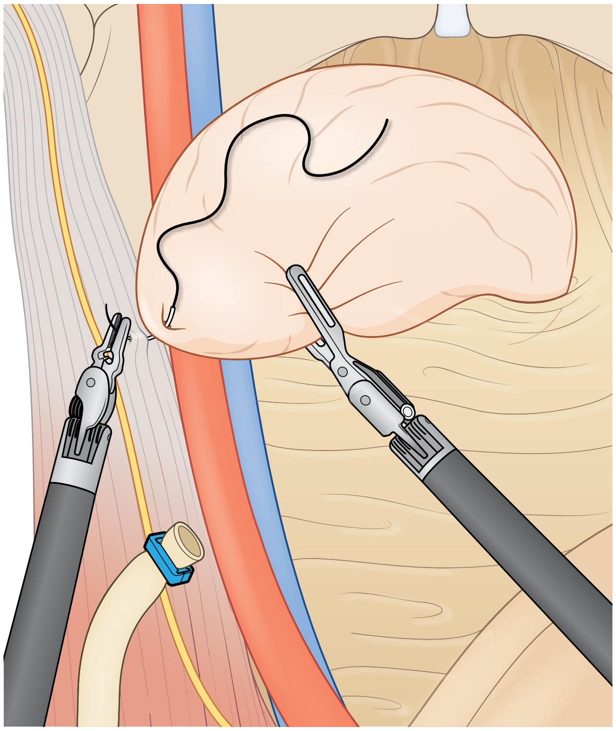

**Figure 117.3** Once the bladder is fully mobilized, it is retracted up to the psoas tendon above the external iliac vessel and sutured in place incorporating both the psoas tendon and the full-thickness musculature and adventitia of the posterior lateral dome of the bladder. We currently employ barbed sutures for anchoring fixation. Care should be taken to avoid entrapment of any nearby nerves.

fascia (Figure 117.3). Alternatively, if the bladder is not easily mobilized up to this position a horizontal cystotomy can be made in its anterior superior ipsilateral dome area and the contralateral fourth arm placed within the bladder and used to retract upward on the bladder to place it juxtaposed to the psoas fascia. This is similar to the open surgical maneuver where the surgeon places their fingers into the bladder to draw the dome superior onto the psoas fascia for securing. This does, however, create an additional cystotomy that will need to be sutured closed in layers.

Once the psoas hitch is in place, if the ureter reaches the dome easily the anastomosis type is at the discretion of the surgeon. One can either perform an onlay type anastomosis directly down onto the most superior portion of the bladder similar to that performed for direct dome ureteroneocystotomy (see Video 117.1) or, using a stay suture on the distal posterior aspect of the anteriorly spatulated ureter, the ureter can be drawn into the bladder through a posteriorly made opening above the psoas, securing with sutures and an intravesical mucosa-to-mucosa anastomosis performed in a "rosebud" fashion. The latter approach, however, does require the use of a more extended cystotomy to allow visualization of the posterior wall of the psoas hitch. We typically perform only refluxing anastomoses as there are no definitive data to suggest that a nonrefluxing anastomosis performs better.

Once the anastomosis is underway, an appropriately sized ureteral stent is brought in and placed up the ipsilateral ureter with the distal curl within the bladder. The surgeon should take into account the shorter distance up into the renal pelvis once the ureter vesicle junction has been moved far superiorly by the psoas hitch. We typically place a stent around 2 cm shorter than would have been standard for patient height. This sizing should minimize the amount of stent in the bladder, although postoperative stent irritation seems rare in these patients, probably due to the amount of mobilization and bladder surgery. Once the anastomosis is completed and the stent placed, any remaining cystotomy is closed with standard two-layer closure of absorbable suture.

In most cases, we prefer at this point to use a barbed absorbable suture for the bladder-to-psoas securing sutures. For the actual anastomosis we prefer either 4-0 or 5-0 interrupted Vicryl or PDS. Closure of the bladder, if a separate cystotomy is done, is performed in two running layers with absorbable suture with a mucosa and then a seromuscular layer running closure. A Foley catheter is left indwelling typically for 10–14 days in our practice, followed by a cystogram confirming bladder closure integrity prior to removal. The stent is left indwelling for 6–8 weeks and removed cystoscopically in the clinic setting.

## Boari flap

The technique for Boari flap formation to allow for replacement of significant distal ureteral loss or involvement with obstruction follows the principles of open surgical performance of this procedure [3]. In any case, where the potential need to bridge a longer distal defect to the level above the iliac vessels exists, this technique is a valuable adjunct. In these scenarios, the surgeon should avoid performance of any cystotomy or incision in the bladder before planning potential flap location and size.

Basic principles of tissue flap creation include using a well-vascularized flap of full-thickness bladder tissue with a broad base to allow for vascular supply to the flap tip, especially with long flaps. We typically perform a crude measurement from the filled bladder (volume of around 200–300 ml) lateral dome to the location of the most distal ureteral transected healthy end, using either a sterile measuring tape, suture, or a known instrument tip length. With the bladder still distended, the location, size, and geometry of the flap are then marked on the bladder with a broad-based area. Care should be taken to not make the tip of the flap too narrow. We typically aim for at least a 2 cm broad tip with a ratio of 1:3 tip-to-base width. In some scenarios, if an extremely long defect is to be reconstructed, a flap may be spiraled from the superior dome (flap base location) down and then across the bladder to create a large spiral flap. In some scenarios authors have even performed these types of flaps to reach all the way to the renal pelvis. Surgeons should be well versed in these operations prior to attempting such long flaps. Other types of approaches, including ileal ureteral substitution or autotransplantation, may also be considered for such extreme ureteral loss.

We typically mark the flap on the surface of the bladder either using a tip from a surgical marker grasped by the robotic instrument or simply marked using the cautery hook or scissors on the seromuscular surface of the bladder (Figure 117.4). We then typically incise the entire seromuscular tissue layer outlining the flap layout prior to dividing the mucosa using cold incision. Once the bladder starts to become decompressed, the surgeon will note extreme shrinkage of the flap. It is therefore essential that the borders of the previous markings be followed as the flap will appear much smaller once the bladder is emptied. Once the flap is formed, the ipsilateral posterior dome area directly below the base of the flap is then anchored to the psoas fascia above the iliac artery similar to a psoas hitch procedure [5]. The flap is then manipulated into juxtaposition with the ureter. The surgeon can then choose the type of anastomosis that suits this situation and the appropriate spatulation direction of the distal ureter, which is commonly anterior. Options include a direct end of ureter onto the tip of the flap. Alternatively, the ureter can be spatulated anteriorly, a traction suture placed on the distal ureteral edge, and a small hiatus created vertically through the posterior superior portion near the tip of the flap. The traction suture is then used to bring the ureter in from posterior to the flap in a tunneled manner (Figure 117.5).

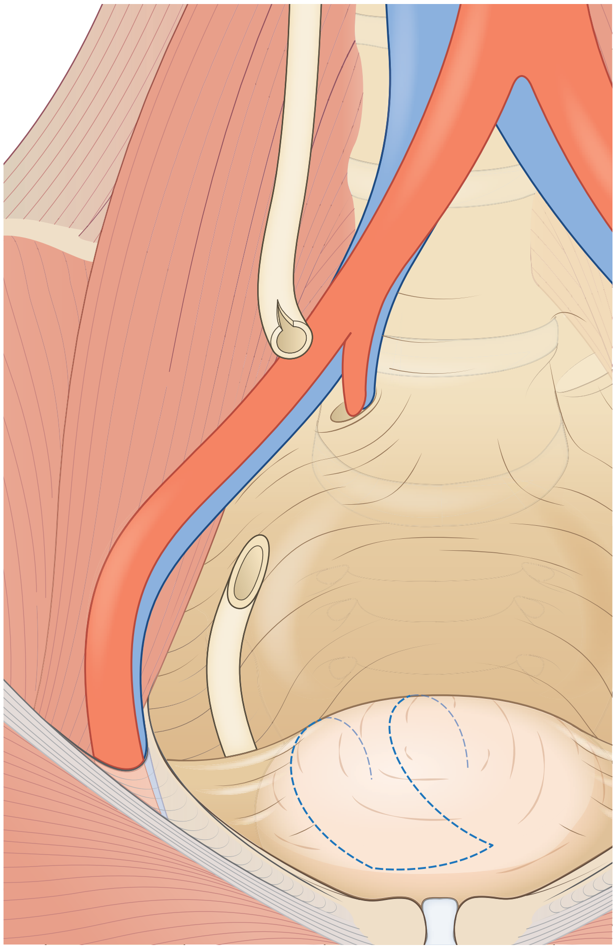

**Figure 117.4** Boari flap. The required flap is marked on the seromuscular surface of the bladder using either a marking pen or cautery. Care should be taken to give the flap a broad-based blood supply. The tip of the flap should be at least 2 cm wide.

We do not attempt to create a non-refluxing submucosal tunnel, but this can be performed if desired, albeit with a slightly higher presumed risk of obstruction. Once the spatulated ureter is brought into the mucosal lumen part of the flap, it can then be "rosebudded," performing an excellent mucosa-to-mucosa anastomosis using interrupted absorbable suture. Prior to rolling the flap, a double-J stent is placed, utilizing the techniques described later. The flap is

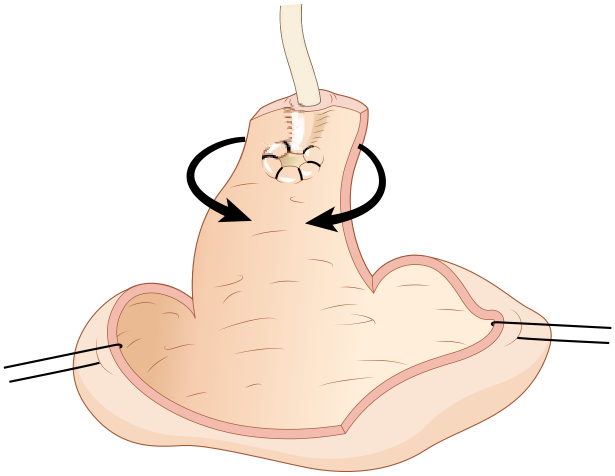

**Figure 117.5** Several methods for approximating the ureter to the flap are feasible. The end of the flap can be tubularized and directly anastamosed end-to-end to the spatulated ureter or, as illustrated here, the ureter is tunneled through the posterior wall of the flap and a "rosebud" type everted mucosa-to-mucosa anastomosis is performed. Once the anastomosis is completed, the flap is tubularized and the residual cystotomy is closed.

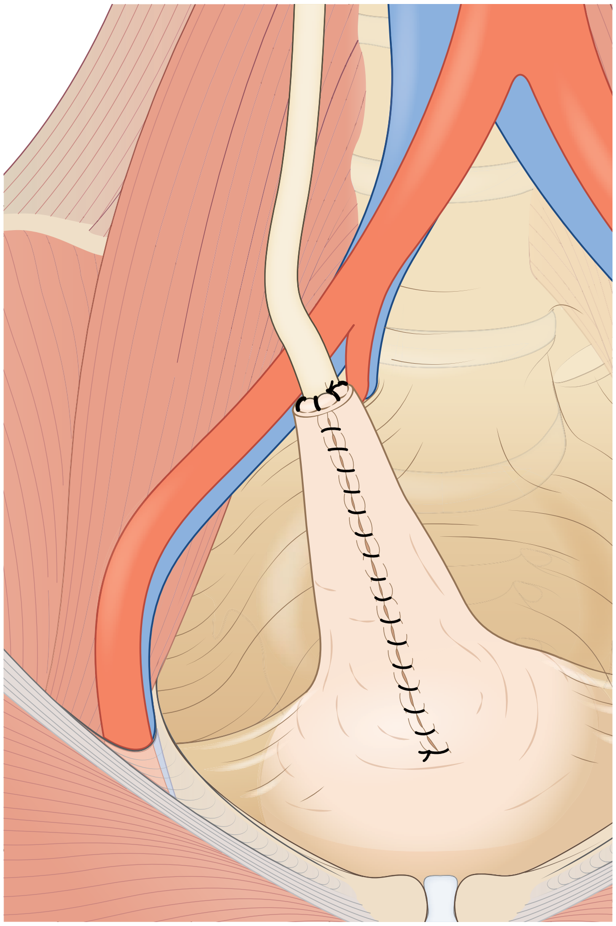

**Figure 117.6** The flap is rolled closed from proximal to distal over the indwelling stent. Following this, the remaining anterior cystotomy is closed in a running fashion. If adequate tissue is available, a two-layer closure can be performed, bringing further seromuscular tissue over the top of the closure suture line. The repair is then leak tested.

then tubularized over the stent that protrudes down into the bladder (Figure 117.6). A stent, typically shorter than the appropriate size stent, is used because the ureter in this scenario is now typically multiple centimeters shorter. The remaining bladder opening is then closed using a standard two-layer absorbable suture approach. The sutures can be run. We are now employing barbed suture for the seromuscular closure. After full closure, the bladder is gently irrigated through the Foley to check for leakage and the Foley is left indwelling. A drain is placed in the perivesical space. We typically leave the Foley for 10–14 days and check with a cystogram prior to removal. The drain is removed when drainage decreases appropriately. Stent remains indwelling for approximately six weeks and is removed cystoscopically in the outpatient setting.

## Stent placement during lower ureteral reconstruction

The majority of repairs use an indwelling ureteral stent placed prior to closure of the anastomosis. Many authors place this by advancing a standard endourology 0.035 guidewire through either one of their assistant trocars or through a small (<3 mm) trocar or stab incision just above the midline pubis. The wire tip is grasped by the robot arms and manipulated up the ureteral lumen. An appropriately sized stent (typically 2–3 cm shorter than for patient height) is then passed by the tableside assistant over the wire and aided into position by the robotic tools.

We employ a slightly different technique, placing a Councill tip Foley at the beginning of the case. At the time of stenting, the guidewire is placed through the Councill and out of the proximal intravesical lumen of the catheter. The wire is then steered via the robotic instrument needle drivers up the ureter. The stent is then placed over the wire and advanced until it can be grasped and manipulated up over the wire and into position. This technique results in the wire and stent having a typically "straight on" angle into the ureteral lumen and, in our estimation, makes passage far easier than fighting against the curves and risking the trauma often induced by coming in through the abdominal wall, which is usually superior and at an acute angle to the partially anastamosed ureter (see Video 117.1 ).

## Discussion

Open surgical ureteral reimplantation into the bladder for benign distal ureteral strictures has been a gold standard with high success rates. These procedures possess the standard postoperative morbidities of a significant abdominal incision, despite being a nonextirpative procedure. Endoscopic interventions expanded during the 1980s and 1990s with the growth of semirigid and flexible ureteroscopy, laser and incisional technologies, and the seminal work of many leaders in the field of endourology. Such endoureterotomy approaches are discussed in other chapters and are typically reserved for shorter strictures (<2 cm) in length.

The initial description of a laparoscopic ureteral reimplantation into the bladder in adults was by Reddy and Evans in 1994 [13]. Other groups then rapidly followed with small case series of laparoscopic distal ureteroneocystotomy [14, 15]. As would be expected with a minimally invasive techniques such as laparoscopy, the authors showed decreases in perioperative blood loss, hospital stay, and requirements needed for analgesia. In 2001, Fugita et al. published the first laparoscopic Boari flap series [16]. Other authors followed with published reports of successful series [15]. However, as with many complex laparoscopic procedures involving suturing and reconstruction, only a small group of highly skilled laparoscopic urologic surgeons were able to perform these procedures utilizing standard laparoscopic techniques. The challenges of learning advance suturing techniques and time-consuming nature of these reconstructive procedures limited more widespread application of laparoscopic reconstruction techniques.

With widespread adoption and market penetration of the Intuitive Surgical da Vinci robotic platform by urologists, multiple authors soon incorporated this advanced computer-assisted surgery into the performance of ureteral surgical reconstruction. Uberoi et al. described their technique of robotic psoas hitch procedure in 2007 [17]. Several multi-institutional consortium groups have subsequently published on larger patient cohorts of robotic ureteral reconstructions [18–20]. Success rates with radiologic follow-up in most series approach 100%.

In summary, the role of minimally invasive reconstruction of distal ureteral pathology using psoas hitch and Boari flap techniques continues to expand and has been aided in adoption by the development of robotic surgical technology. These advances, developed by visionary laparoscopic surgeons, have been further enabled by the increasing widespread use of robotics and are now standard at many institutions. New and even more advanced techniques, such as robotic ureteral buccal grafting, ileal ureteral substitution, and autotransplantation are now at the leading edge of technique advancement [9–12].

# Laparoscopic Management of the Undescended Testicle

*Brian A. VanderBrink*

*University of Cincinnati School of Medicine, Cincinnati Children's Hospital Medical Center, Division of Urology, Cincinnati, OH, USA*

## Introduction

An undescended testicle on physical examination is reported in between 2% and 5% of full-term and 30% of premature male infants [1]. There is increasing prevalence of cryptorchidism with low birth weight. Infants with birth weight under 2000 g were found to have undescended testicle in 7.7% of patients at three months of age, compared to 1.4% of infants with birth weight over 2500 g [2]. Cryptorchidism is more frequently a unilateral finding than bilateral finding, and approximately 20% of boys who present with cryptorchidism have at least one nonpalpable testis [3–5]. When identified in the newborn setting, standard of care is observation as spontaneous descent can be seen over time. Studies have reported rates of 45–75% of spontaneous descent when examined serially [6, 7]. In contrast, Wenzler et al. observed spontaneous descent in only 7% of undescended testicles presenting in infants when re-examined at 1 year of age, with all observations occurring in patients that presented less than six months of age [8].

However, surgical intervention is indicated when spontaneous descent does not occur as early surgical intervention confers growth advantage to the cryptorchid testicle compared to delayed surgery. When the undescended testicle is not palpable, the undescended testicle may be intra-abdominal or absent/atrophic. In one retrospective study of 447 nonpalpable testes, 40% were atrophic or absent, 20% were intra-abdominal, and 40% were found to be canalicular, scrotal, or ectopic testes at the time of surgery [5]. Historically, an open laparotomy was performed in patients with nonpalpable undescended testicles to address an intra-abdominal testicle if present. Cortesi et al. in 1976 were the first to describe laparoscopy for diagnostic purposes to determine whether a viable testicle was present [9]. Therapeutic laparoscopy for a nonpalpable undescended testicle was then described by several investigators soon after and this allowed minimally invasive therapeutic surgery to be applied to urology [10, 11]. This chapter reviews the diagnosis and management of the child with nonpalpable undescended testicle.

The combination of an undescended testicle and hypospadias merits specific mention due to its association with disorders of sexual development (DSDs). Kaefer et al. observed a significant increase in frequency of DSD conditions with more proximal location of the undescended testicle, with the highest observed association for a nonpalpable cryptorchid testicle and hypospadias [12]. Therefore, when cryptorchidism and hypospadias are identified in the same patient, whether palpable or nonpalpable, a karyotype is mandatory to rule out a DSD. Further diagnostic workup is beyond the scope of this chapter.

## Preoperative assessment

A thorough history is the initial part of any patient encounter. The pertinent aspects for the patient with an undescended testicle are a birth history (full term or premature), birth weight, a family history of cryptorchidism, the patient's own medical/surgical history and any genetic syndromes. Prior physical examination findings will be important information to know as well to gauge whether the condition is improving or not.

The physical examination is the most critical component of the diagnostic workup for the cryptorchid testicle. Ensuring that the patient is calm and cooperative, especially in the pediatric age group, allows for more confidence in the observed exam findings. The examiner's hands and fingers must be in the proper position for an

Companion website: www.wiley.com/go/smith/textbookofendourology

appropriate examination of the scrotum. Ideally, the index finger and/or middle finger of the examining hand are placed over the posterior aspect of the scrotum, with the thumb of that hand positioned over the anterior aspect of the scrotum.

If the testicle is not palpated in the scrotum, the inguinal canal should be examined for retained testicular tissue. For the right-handed individual, with the index and middle finger of the examiner's left hand positioned over the inguinal canal, the examiner should palpate the length of the canal while inferomedially sweeping in an attempt to trap the testicle along its projected line of normal descent and if possible express any retained testicular tissue into the scrotum. At the same time, the middle finger, index finger, and thumb of the right hand should be properly positioned to palpate the ipsilateral proximal scrotum for any testicular tissue entering from the inguinal canal. Reducing friction between the examiner's fingers and the inguinal canal by placing soap on the fingertips can increase the likelihood and sensitivity of palpating an undecended inguinal testicle. If the examiner has difficulty palpating scrotal testes in the older child, the patient should be placed in a sitting knee–chest position to help force the testes into a dependent position or, while seated leaning forward, in crossed-leg position ("tailor's position").

The decision regarding orchiopexy versus orchiectomy in a postpubertal male who presents with unilateral postpubertal cryptorchidism must be made on an individual basis and based upon the health of the contralateral testicle, competing medical comorbidities and fertility/paternity status of the man. The cryptorchid testicle should be saved if it is the only source of testosterone and/or sperm (i.e. if the contralateral testis is absent or abnormal). On the other hand, if the contralateral testis is normal, orchiectomy may be beneficial to avoid potential development of malignancy or torsion. A discussion with the patient about surgery while discussing risks and benefit of surgery is needed while accounting for risks of general anesthetic accounting for patient age and competing comorbidities when present. In certain instances when the crytorchid testicle is identified later in life the theoretical risks of an anesthetic complication may outweigh the risk of malignancy from the intra-abdominal testicle, making observation a third viable option [13].

## Laparoscopic surgical technique for the nonpalpable testicle

Following induction of anesthesia, repeat physical examination is performed to confirm a cryptorchid testicle and to determine whether it is palpable or nonpalpable. Surgical technique is modified accordingly to exam findings. Cisek et al. reported that a nonpalpable undescended testicle in clinic became palpable with exam under anesthesia in 40 patients of their 225 patient series [14]. A palpable undescended testicle will not benefit from laparoscopy and should receive an inguinal exploration. If the testicular examination demonstrates a nonpalpable testicle than proceeding with a diagnostic laparoscopy is indicated. Perioperative antibiotic prophylaxis is recommended and given prior to incision. Drainage of the bladder through urethral catheterization may help minimize bladder injury during the procedure. Although the use of laparoendoscopic single-site (LESS) surgery for orchiopexy utilizing a single access point for the camera and trocars has been described [15, 16], the surgical technique described in this chapter is standard multiport laparoscopic orchiopexy.

Pneumoperitoneum can be established via Veress needle placed through rectus fascia at the umbilicus or open Hassan technique. Each technique has their own advantages and disadvantages, as described elsewhere (Chapter 84). Following creation of pneumoperitoneum, the placement of the initial trocar through the umbilicus for the laparoscope permits visual inspection of the pelvis and both internal inguinal rings. Putting the patient in Trendelenburg position will allow for intestine to be displaced cranially while inspecting the pelvis. During the intraoperative inspection of the pelvic anatomy the surgeon should be focused on identifying the testicular blood vessels as this will dictate the proper sequence of events. Inspection of the normal contralateral side for a unilateral undescended testicle will assist in acquiring normal orientation under the assumption there is no contralateral occult pathology.

Most commonly, three possible scenarios are encountered for the nonpalpable undescended testicle upon diagnostic laparoscopy. The first is vessels leading to an intra-abdominal testicle that typically is found within a few centimeters of the internal ring (Figure 118.1a). The laparoscopic identification of an intra-abdominal testicle permits planning for the definitive procedure and additional trocar placement if laparoscopic orchidopexy or orchiectomy is pursued. The second situation is gonadal vessels that end blindly in the retroperitoneum, indicating that there is no testicle present (Figure 118.1b). Third, the vessels may lead to and exit through the internal inguinal ring into the inguinal canal (Figure 118.1c). Inguinal exploration is carried out if testicular vessels and vas deferens are visualized exiting the internal ring. In one review, 27 patients with 30 nonpalpable testes underwent laparoscopy after previous negative inguinal exploration with the findings of one-third of patients had blind-ending spermatic vessels, one-third had viable intra-abdominal or inguinal testes, and one-third had intra-abdominal remnants [17].

Further mobilization of the intra-abdominal testicle is accomplished with additional working trocars placed under direct vision with laparoscope. Three or five millimeter trocars can be placed, depending upon the size of the patient, surgeon preference, and whether introduction of a laparoscopic clip applier is anticipated. If the latter is expected then a 5 mm trocar is a better choice. The placement of the working trocars on the abdominal wall depends on whether a unilateral or bilateral procedure will be performed. Trocars placed in the midclavicular line at the level of the umbilicus on each side of the abdomen enable the surgeon to change sides when bilateral orchidopexy is indicated (Figure 118.2). Alternatively, simple incisions in the abdominal wall allow for passage of laparoscopic instruments without using ports [18].

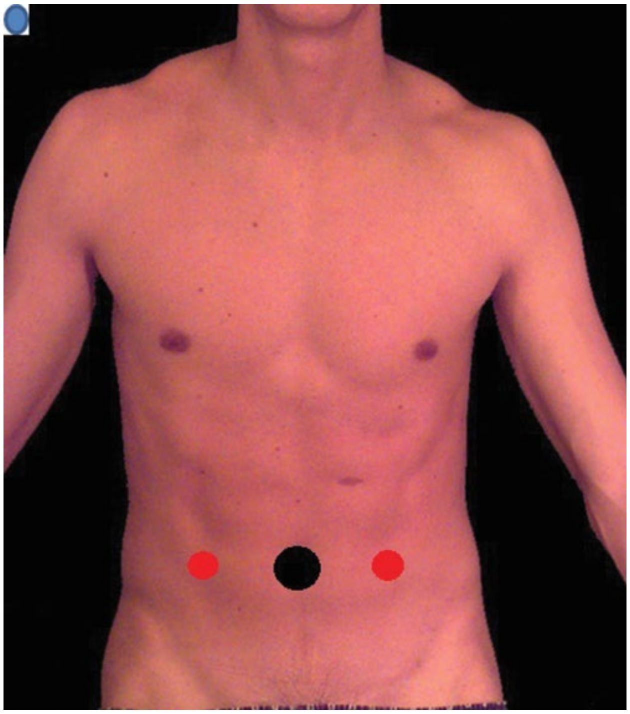

**Figure 118.2** Diagrams of trocar placement for laparoscopic orchiopexy. An umbilical trocar (black circle) allows for inspection of pelvic and abdominal structures. Trocars placed in the midclavicular line at the level of the umbilicus on each side (red circles) enable the surgeon to change between sides when bilateral orchidopexy is indicated.

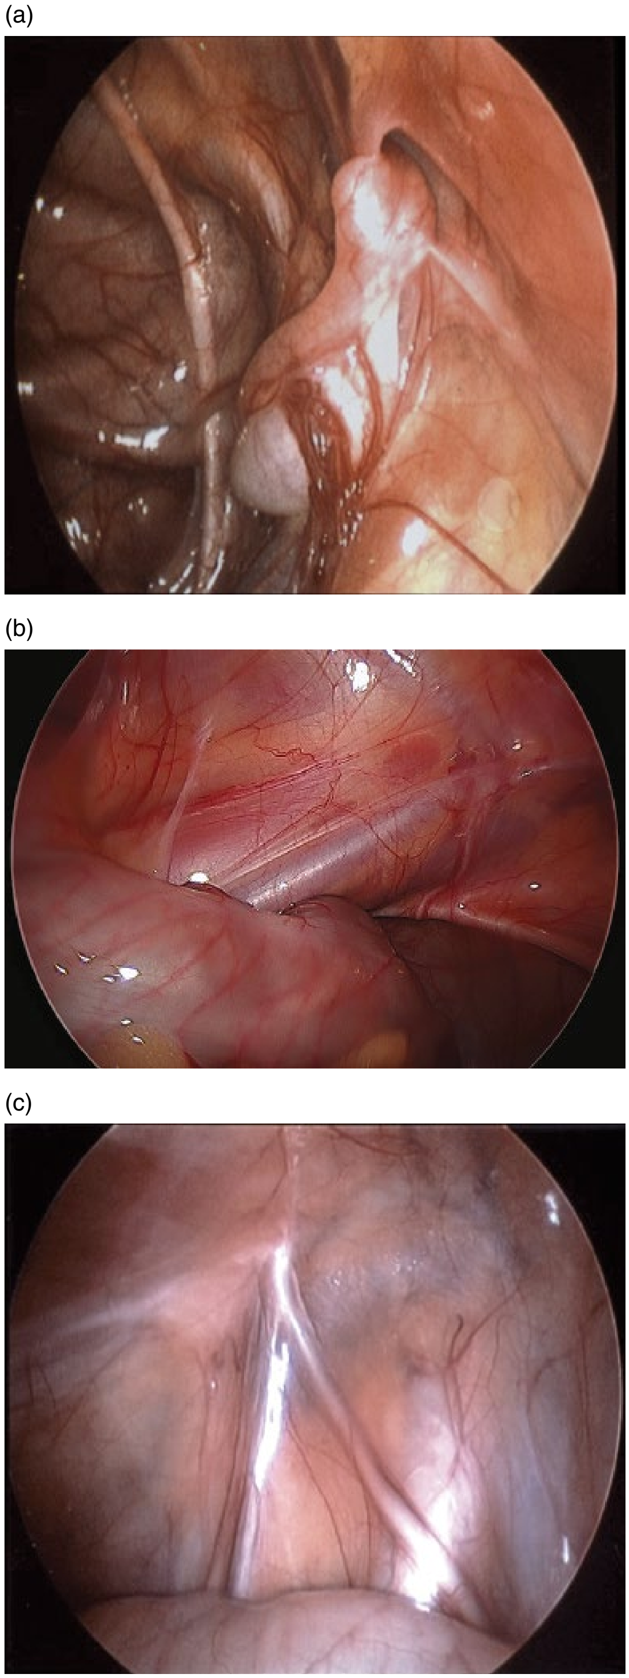

**Figure 118.1** (a) Intraoperative image of intra-abdominal testicle that typically is found within a few centimeters of the internal ring. (b) Intraoperative image of testicular vessels that end blindly in the retroperitoneum, indicating that there is no testicle present. (c) Intraoperative image of testicular vessels leading to the internal inguinal ring and exiting through the internal inguinal ring into the inguinal canal

This may lower operative costs, possibly improves cosmesis, and reduces the risk of port-site hernias.

The tunica albuginea of the testicle can be grasped using an atraumatic grasper to provide traction and more accurately ascertain its proximity to the internal ring. Grasping other structures such as epididymis or vas risks their injury given their delicate nature and should be avoided. Intuitively, the difficulty in placing the intra-abdominal testicle into the scrotum increases as the distance from the scrotum increases. The need to perform a Fowler–Stephens technique rises as the distance of the intra-abdominal testicle from the internal ring increases and this will be discussed more in depth later in the chapter. However, it is critical for the surgeon to integrate the information obtained during the diagnostic laparoscopic portion, such as size of testicle, distance of testicle from internal ring, and spermatic cord anatomy, in order to determine if a one-stage or two-stage laparoscopic orchiopexy is best for the patient.

## Laparoscopic orchiopexy technique (see Video 118.1)

Caudal to the intra-abdominal testicle the gubernacular attachments are closely examined as they enter the inguinal ring when present. The optical magnification of the laparoscope assists in differentiating between the gubernaculum and vas deferens; however the surgeon must be cognizant that risk of injury to the delicate Wolffian structures is always present during the dissection. Division of the gubernaculum is typically performed with the use of cautery, depending upon the surgeon's discretion. After the gubernaculum has been divided this can serve as a handle for elevating the tissue cranially during further dissection, which minimizes the need for manipulation of delicate Wolffian structures. Incision of the peritoneum lateral to the intra-abdominal testicle enters the retroperitoneum and further mobilization is facilitated with use of blunt dissection off the iliac vessels. The dissection is expanded cranially along the lateral border of the gonadal vessels. Incision of the peritoneum inferiorly in a plane parallel to the vas deferens from the internal ring towards the obliterated umbilical ligament occurs next. Additional dissection is carried out with the aim of maintaining a wide swathe of peritoneum in the shape of a triangle between the vessels and vas, with the testicle being the apex. The peritoneum over the proximal gonadal vessels can be divided, releasing any tension and at times affording additional length. This last maneuver can be accomplished after the testicle is moved out of the abdomen when the sites of tension on the cord are best appreciated.

There have been various techniques for moving the testicle out of the abdomen into the scrotum. One described technique involves bringing the testicle through the internal inguinal ring into the inguinal canal and scrotum, similar to standard inguinal orchiopexy. Another frequently employed technique is to create a neohiatus through the abdominal wall directly over the pubic tubercle into the ipsilateral scrotum. Directing the testis through this new, straighter path created above the pubic tubercle rather than following the longer course through the internal inguinal ring and inguinal canal can potentially add 1–2 cm of length, which makes the difference between a tensioned and tension-free testis placement in the scrotum. Pertinent anterior abdominal wall anatomical landmarks while making the neocanal are the inferior epigastric vessels, medial umbilical ligament, and bladder. Decompression of the bladder will help minimize its inadvertent injury when the neocanal is created between the lateral edge of the bladder and medial umbilical ligament. The canal can be created from inside the abdomen outwards or vice versa under direct laparoscopic view. An incision in the scrotum is made and a hemostat or Kelly clamp can be used to bluntly create a defect in the anterior abdominal wall anterior to the pubic tubercle through this incision. Upon entering the abdomen through this neohiatus, the clamp can be used to grasp the gubernacular attachments for pulling the testicle into the scrotum. Alternatively, a laparoscopic instrument can bluntly penetrate the anterior abdominal wall over the pubic tubercle and exit the scrotum. At this point a hemostat can be locked onto the laparoscopic instrument and fed through the abdominal wall defect to expand the diameter of the neocanal, allowing the testicle to exit through it. Opening the hemostat can widen the neohiatus enough to allow the testicle to pass through without injury. Instillation of saline into the bladder to fill it allows the surgeon to identify any injury to the bladder intraoperatively and repair it. Creation of the neocanal medial to the inferior epigastric vessels, but lateral to the medial umbilical ligament would likely minimize the risk of bladder injury.

A superficial dartos pouch for the testicle to reside in is created after incising the scrotal skin with the use of hemostat. After the testicle is brought into the scrotum and into the pouch it can be affixed to the scrotal skin, ideally without tension to minimize risk of postoperative ascent. The technique of scrotal testis fixation is important, especially when initially there is a high testis. The author prefers the use of nonabsorbable monofilament suture, passed superficially through the lateral and medial sides of the testis and sutured to dependent portion of dartos pouch. The use of an absorbable suture is reasonable as there is no evidence that nonabsorbable sutures are superior. Placement of these tunical fixation sutures transcutaneously through a gauze fixation pledget or sterile button over the scrotum has been utilized to assist in healing in a scrotal position when tension-free placement in the dartos pouch cannot be accomplished.

After the testicle is secured into its scrotal position the abdomen is surveyed one final time, searching for sites of bleeding from laparoscopic dissection. The ipsilateral open inguinal ring does not need to be closed as clinical inguinal hernias are not evident, despite the patency demonstrated on laparoscopy. Khairi et al. reviewed nearly 400 laparoscopic orchiopexy cases with near equal distribution of testicles passed through the internal inguinal ring into the scrotum or neohiatus medial to native internal ring [19]. After over 3 years follow-up for each technique there were no cases of inguinal hernia in any patient. The contralateral inguinal ring has been demonstrated to be patent in 9–33% of patients, with increasing rates in patients younger than 2 years [20, 21]. Concurrent laparoscopic repair of the patent processus has been reported [21].

Hemostasis is obtained as needed and each working trocar is removed under direct laparoscopic view. Although radial-dilating trocars that are 3–5 mm in diameter have been purported by manufacture not to result in abdominal wall defects that lead to hernias, the author routinely closes the trocar fascial defects under direct laparoscopic vision with suture ligature. The umbilical trocar and laparoscope are removed together and the trocar site closed. Skin incisions are closed according to surgeon's preference.

## Fowler–Stephens technique for inadequate testicular vessel length

A high intra-abdominal undescended testicle with short testicular vessels may require a Fowler–Stephens technique, either in a one-stage or two-stage approach to achieve a position within the scrotum after laparoscopic orchidopexy. The need to perform a Fowler–Stephens technique rises as the distance of the intra-abdominal testicle from the internal ring increases. A distance of greater than 2 cm was an indicator of inadequate testicular vessel length for primary laparoscopic orchidopexy in one study [22]. Another purported visual cue suggested to check for sufficiency of the testicular vessels to reach the scrotum is to grasp the testicle and seeing if it can be extended to the contralateral inguinal ring prior to any dissection [23]. The rationale behind this maneuver is that if the testicular vessel demonstrates that amount of laxity then there should be enough length to achieve scrotal position. Unfortunately, the testis will not reach the contralateral internal inguinal ring prior to dissection in most cases, so this cannot be used as the sole indication for Fowler–Stephens procedure in all cases. In fact Yucel et al. reviewed their outcomes of laparoscopic orchiopexy in 46 testicles, where only 20 testicles reached the lower scrotum and the remainder the upper scrotum, to identify any intraoperative predictors for successful lower scrotum outcome [24]. The authors found that patient age, location within 2 cm of the internal ring, or mobility of the testicle to the contralateral inguinal ring were not predictive factors to bring the testicle to the lower scrotum. Atrophy was identified during follow-up in six testicles (14%) and secondary procedure was performed for position at or above the upper margin of the scrotum in five patients (12%).

A recent single-surgeon series of an innovative technique has been described to lengthen the vessels prior to orchiopexy. Shehata et al. describe a staged laparoscopic traction orchiopexy entailing fixation of the testis to a point 1 inch (2.5 cm) above and medial to the contralateral anterior superior iliac spine on the anterior abdominal wall for 12 weeks [25]. The second stage involves division of the traction suture and delivery of the testicle out of the abdomen and into the scrotum with a subdartos orchiopexy. The technique has been applied to 140 testes in 124 boys with a scrotal position achieved in 84% of the patients (mean follow-up of 16 months). Distance of testicle from internal ring 0–2 cm achieved 93% (80/86) success, 2–4 cm achieved 78% (25/32) success, and very high intrabdominal testicles that were >4 cm from internal ring were unsuccessful in all cases 0% (0/7).

The Fowler–Stephens technique is predicated on the multiple arterial blood supply to the testicle. The testicle has three arterial sources: the testicular artery originating from the aorta, the cremasteric artery from the inferior epigastric artery, and the vasal artery from the superior vesical artery (Figure 118.3). Early decision for deliberate transection of the testicular vessels is essential before mobilization of this collateral blood supply that is derived from the pelvic collaterals.

A staged orchiopexy in which the testicular vessels are ligated to allow for sufficient testicular mobility was first described by Fowler and Stephens in 1959 [26]. Ligation of the testicular vessels is usually performed with a laparoscopic clip applier and typically performed cranial to the testicle well away from the critical collateral vessels arising inferior-medially to the testicle. Immediate further mobilization of the testicle with aforementioned surgical technique with an emphasis on wide mobilization of the testes and adjacent peritoneum can be performed for the one-stage Fowler–Stephens laparoscopic orchiopexy.

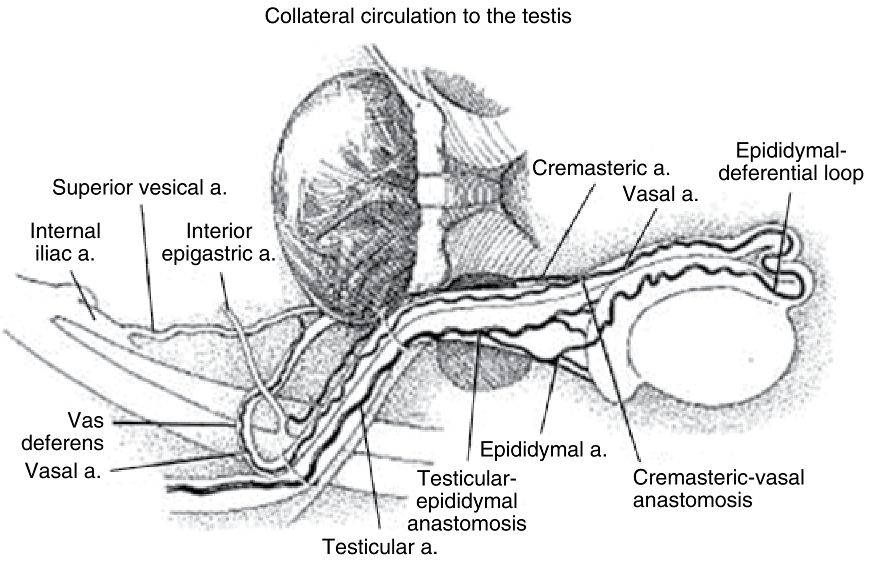

**Figure 118.3** The testicle has three arterial sources, the main being the testicular artery originating from the aorta. There is also the cremasteric artery that originates from the inferior epigastric artery and the vasal artery that originates from the superior vesical artery. *Source:* Hima F. *Atlas of Urosurgical Anatomy*, 497. London: Elsevier, 1993. Reproduced with permission of Elsevier.

Alternatively, ligation of the vessels and an intentional two-stage approach can be pursued, allowing for an increase in collateral blood flow over time now that the main arterial blood supply has been interrupted. This has been associated with lower rates of testicular atrophy than a single-stage technique. After approximately six months, the second stage laparoscopic orchiopexy is performed. Access is obtained through the previous laparoscopic trocar sites and the testicle inspected. If significant atrophy is noted then laparoscopic orchiectomy can be performed, as further mobilization of the testicle may not result in viable testicle following placement into the scrotum. Atrophy rates following division of testicular vessels has been reported and orchiectomy performed laparoscopically when this is encountered. Mobilization of the testicle with preservation of a wide swathe of peritoneum around the testicle and vas deferens is critical to avoid injury to the collateral blood vessels that now serve as sole blood supply to it. Regardless of whether a one-stage or two-stage approach is taken, the creation of the neocanal and scrotal fixation is performed according to the aforementioned techniques.

## Laparoscopic orchiopexy outcomes

There have been many published reports since the first description of laparoscopic orchiopexy by Jordan et al. [10]. Table 118.1 summarizes a few selected contemporary series [27–39]. Some series have compared historical open orchiopexy outcomes to pure laparoscopic technique. A systematic review of whether a staged Fowler–Stephens orchiopexy was more beneficial was reported by Elyas et al. [40]. Using electronic queries of published surgical series, the pooled estimate of success rates was 80% for single-stage Fowler–Stephens orchiopexy compared to 85% for two-stage Fowler–Stephens orchiopexy. Statistical analysis of the pooled odds ratio (OR) favored a two-stage Fowler–Stephens orchiopexy for adequate postoperative testicular size and scrotal position (OR 2.0, 95% confidence interval 1.1–3.9).

## Conclusions

The nonpalpable undescended testicle remains an important clinical situation for the treating physician. Identification of intra-abdominal testicle is critical to counseling patient and families regarding malignancy risk, and moving the testicle out of the abdomen and into the scrotum may preserve fertility. Laparoscopy offers an advantage over radiographic studies in that it has higher sensitivity and allows for therapeutic maneuvers at same setting. A minimally invasive approach confers a theoretical cosmetic and analgesic advantage over traditional open transabdominal orchiopexy. Several studies have demonstrated outcomes for laparoscopic orchiopexy equivalent to those of open orchiopexy for the intrabdominal testicle whether or not a Fowler–Stephens technique is applied. The widespread dissemination of laparoscopic surgical techniques and training with them during residency and fellowship programs make the laparoscopic management of nonpalpable undescended testicle increasingly first-line treatment when resources allow for its implementation.

## Introduction

Varicoceles are abnormally dilated veins of the pampiniform plexus. They are primarily lateralized to the left side perhaps due to an anomalous valvular mechanism as the blood drains into the left renal vein. The prevalence of varicoceles increases through puberty from 8% to equal the prevalence of the adult population, approximately 15%, by the age of 15–19 years. Evaluating and treating varicoceles thereby comprises a significant proportion of problems presenting to the practicing pediatric urologist [1, 2]. In pediatric patients, varicoceles pose several intriguing conundrums: observe versus treat, if treat when to intervene, if treat what modality to use, and what is the evidence that treatment helps fertility, testicular volume, or symptoms? Significant correlation exists between testicular hypotrophy and altered semen parameters [3]. A body of evidence implies that a cohort of patients will demonstrate catch-up growth and spontaneous improvement of semen parameters and thus warrant observation only; yet, the parameters defining that group remain unclear [3–6]. Furthermore, there are conflicting data as to whether the testicular artery should be spared or not, as sparing may increase the risk of recurrence but has also been shown to improve semen parameters [7–9]. In addition, when specifically examining management approaches there are several to choose from: microsurgical subinguinal (Goldstein), inguinal (Ivanissevich), abdominal (Palomo, nonartery sparing), surgical antegrade sclerosis, radiographic retrograde embolization, and laparoscopic (complete ligation vs. artery/lymphatic-sparing). In a recent survey of pediatric urologists, there was no consensus as to the best surgical approach, with 38% of practitioners reporting the laparoscopic approach as their preferred method while 28% used subinguinal microsurgical, 14% inguinal, and 13% retroperitoneal (13%) [10]. This chapter focuses on the laparoscopic approach, which is the most frequently used method of treatment.

Laparoscopic varicocelectomy was first reported in 1988 with several technical refinements subsequently described [11–14]. The advantage of this approach is that magnification can improve the identification of the vessels and enhance the ability to spare lymphatics and/or the testicular artery. The disadvantages include a steep learning curve for physicians not exposed to laparoscopic techniques, as well as possible injury to the intra-abdominal organs. However, recent meta-analyses have deemed it a safe procedure in previously explored abdomens as well as effective in limiting hydrocele formation and varicocele recurrence [15, 16].

## Indications

Although clear indications exist for consideration for a varicocelectomy in adults, as outlined by the American Urologic Association (AUA) guidelines, which are mainly based on fertility testing, there is very little guidance for the pediatric patient aside from noting that varicocelectomy may be offered due to testicular size discrepancy [17]. However, these recommendations are nonspecific and are at variance with common clinical practice; when patients present with testicular asymmetry associated with a varicocele, 32% of practitioners intervene immediately despite data indicating that 85% of adolescent males presenting with greater than a 15% testicular size discrepancy will become normal after 2 years of observation [5, 6].

There are noteworthy differences between the pediatric and adult population; most adolescents present asymptomatically (the "bag of worms" finding on routine exam) and without a fertility question, whereas in the adult population fertility evaluations disclose varicoceles

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.
© 2019 John Wiley & Sons Ltd. Published 2019 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/smith/textbookofendourology

in up to 35% of men found to be subfertile [18]. In addition, whereas assessing semen analysis is common in the adult population, only 13.1% of practitioners routinely obtain a semen analysis on adolescents with varicoceles. Furthermore, 48% of practitioners report discomfort discussing this issue with their adolescent patients and parents [19]. These differences highlight the difficulty in managing and knowing when to operate on a pediatric patient.

A closer examination of the question of surgical timing comes from a recent review by Kolon, who advocates for repair of the adolescent varicocele once the child is Tanner stage V and the total testicular volume is low, semen parameters are low, androgen laboratory results are abnormal, or the patient is symptomatic (rare) [2]. However, only 10% of pediatric urologists send semen for analysis at <17 years [5]. Although Kolon's review puts more weight on persistent abnormal semen analysis focusing on total motility counts (TMC) below 20 million and waiting until the patient reaches at least Tanner V maturity, others have used the testicular volume percent difference ($\text{TV}_{\text{diff}}$) as cut-off [2]. Diamond et al. found a correlation between a percent volume difference measured via ultrasound of >10% and lower TMC. However, at the 10% cut-off there would be a considerable number of patients with normal semen parameters. Hence some authors advocate for 20% $\text{TV}_{\text{diff}}$ as there was an inverse relationship between $\text{TV}_{\text{diff}}$ and TMC [3]. It is worth noting that Christman et al. followed 73 adolescent patients serially for a median of 2.7 years and was not able to reproduce the same finding [20]. They conclude that during adolescence there is too much variability to accurately assess future semen parameters; however, they do note that if the total testicular volume is low there is a significant correlation with low TMC.

Another parameter explored for indication for varicocelectomy is venous backflow. Van Batavia et al. reported that 50 of 53 adolescents with $\text{TV}_{\text{diff}}$ of >15% and peak retrograde flow greater than 38 cm/s failed to demonstrate catch-up growth after mean follow-up of 15.5 months [21]. These patients may be at risk for future fertility problems. Last, although rare in the adolescent population, pain is a consideration for varicocelectomy.

## Anatomy

Each variation of varicocelectomy takes into account the complex vasculature of the testis. Varicoceles develop when the pampiniform plexus experiences increased venous backflow and dilates due to elevated pressures. While the right internal spermatic vein drains directly into the inferior vena cava, the left internal spermatic vein connects to the left renal vein where backflow is higher. Hence, the majority of varicoceles are left sided. Consideration of a retroperitoneal mass or other pathology is indicated when there is a right-sided varicocele, and although pathology is rare we recommend retroperitoneal imaging when present [22]. Although the pampiniform plexus, eventually becoming the internal spermatic vein, is the main drainage of the testicle, the testicle and epididymis are also drained by the posterior spermatic plexus which flows into the external iliac vein and the cremasteric vein which drains into the pudendal vein. These collaterals allow for venous return following varicocelectomy.

The arterial blood supply to the testis is also complex, with blood coming from three arteries: (i) testicular artery from aorta; (ii) deferential artery from either the superior or inferior vesical artery off the internal iliac; and (iii) cremasteric artery from inferior epigastric artery. Thus, if the testicular artery is sacrificed, as in the Palomo repair, the testicle still receives adequate blood flow. Last, the primary lymphatics channels follow the testicular artery and hence can be confidently spared via a laparoscopic approach.

## Surgical procedure

The patient is brought into the operating suite after emptying his bladder. Following induction of general anesthesia, the patient remains in the supine position with his arms tucked. We prefer that both the surgeon and the assistant stand on the contralateral side from the varicocele. If desired, the patient may have a jell roll placed on the ipsilateral side of the varicocele to help keep the bowel away from the operative field (Figure 119.1; see Video 119.1). The required instruments are listed in Box 119.1.

Although this procedure has been reported using a single-site 20 mm port method, a three-port approach remains the most common [23, 24]. We place 5 mm trocars in the umbilicus, the right lateral rectus margin approximately 2 cm below the umbilicus and another port just superior to McBurney's point. This positioning and trocar placement can be mirrored for an isolated right-sided varicocele. For a bilateral varicocele repair, trocars are placed in the umbilicus, right and left lateral rectus margins approximately 2 cm below the umbilicus. An alternative trochar placement strategy is an umbilical port, one placed at the right lateral rectus margin about 2 cm from the umbilicus, and one placed midline approximately 8 cm below the umbilicus. In this case the camera is transferred from the umbilical trocar to the right lateral trocar when transitioning from operating on the left varicocele to the right side.

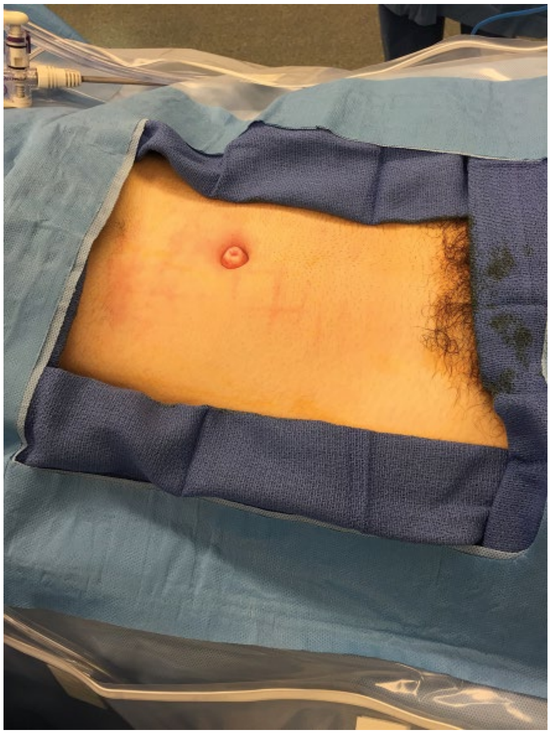

**Figure 119.1** Prepped and draped patient.

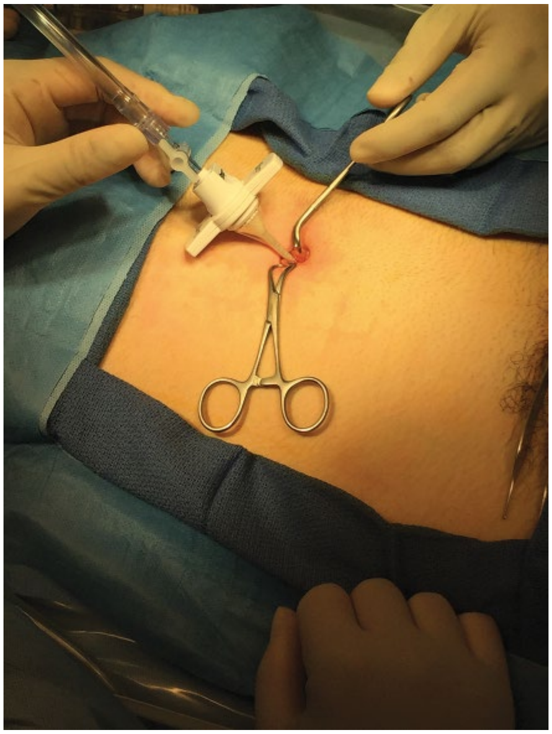

**Figure 119.2** Placement of 5 mm umbilical port: evert the umbilicus with towel clamps and make a 5 mm vertical incision using electrocautery down through to the fascia and place the Veress needle.

**Box 119.1 Instruments.**

- Electrocautery

- 5 mm tocars × 2
- VeraStep™ 5 mm trocar
- 30° lens and camera
- 5 mm clip applier or LigaSure™
- 5 mm monopolar Endo Shears™
- Maryland grasping forceps
- Optional: laparoscopic Doppler

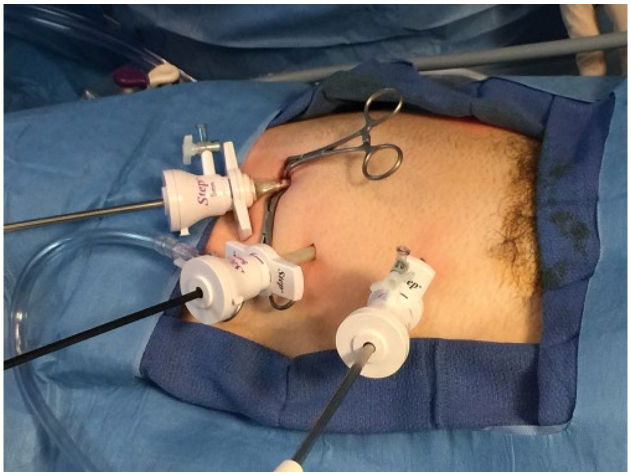

**Figure 119.3** Port placement for left-sided laparoscopic varicocelectomy.

Starting at the umbilical site, we evert the umbilicus and make a 5 mm vertical incision using electrocautery down through to the fascia (Figure 119.2). We use a 5 mm VeraStep Veress needle to insufflate with $CO_2$ at a rate of 3 l/min to a pressure of 10–15 mmHg, depending on the patient's body habitus. Once adequate pneumoperitoneum is achieved, the needle is exchanged for the 5 mm trocar in the nonslip sheath. A 30° lens is placed through the umbilical trocar and the other two 5 mm trocars are placed under direct vision with careful attention to avoid bowel and the inferior epigastric vessels (Figure 119.3). After inspection of all entry points and adjacent structures to ensure no damage, we look for closed internal rings bilaterally. Slight Trendelenburg position helps to allow the bowel to fall away from the cord. After identifying the spermatic cord and the vas deferens, a Maryland grasper is placed through the superior trocar and scissors in the inferior trocar and an incision is made in the posterior peritoneum over the spermatic cord vessels approximately 5 cm superior to the internal ring

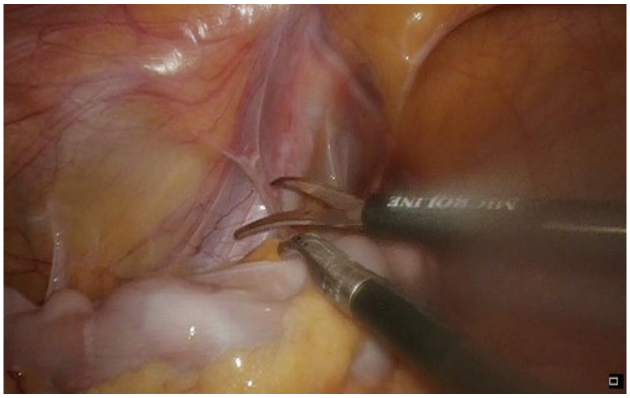

**Figure 119.4** Isolating the cord. Incise the posterior peritoneum over the spermatic cord vessels approximately 5 cm superior to the internal ring.

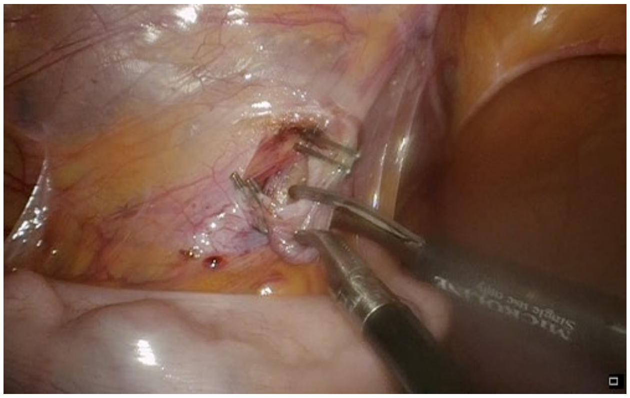

**Figure 119.5** Complete spermatic cord ligation. Place two 5 mm clips superior and two clips inferior and ligate the spermatic cord vessels when performing a complete ligation.

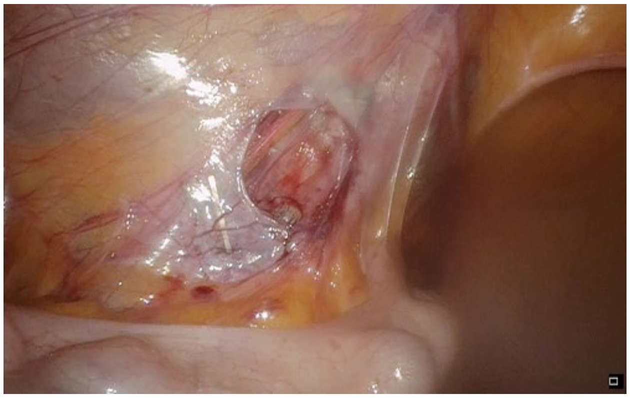

**Figure 119.6** Final inspection. Hemostasis is achieved and the clips are then tucked under the peritoneum to avoid contact with the bowel.

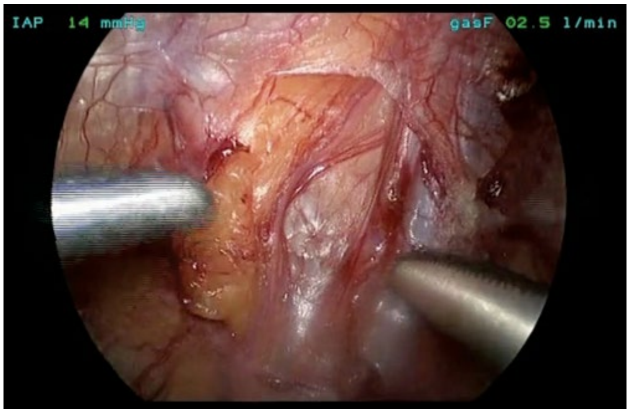

**Figure 119.7** Sparing the lymphatics. The lymphatic channels are small, translucent vessels lateral to the artery and vein.

(Figure 119.4). Once the cord is isolated for a distance, two 5 mm clips are placed superiorly and two clips inferiorly and the gondal veins is divided (Figure 119.5). In cases where the bundle is wider than the length of a clip, the clips are applied and the cord is partially transected and then another series of clips are applied to complete occlusion of the cord both proximally and distally and the cord severed. After inspecting for hemostasis the clips are then tucked under the peritoneum to avoid contact with the bowel (Figure 119.6). The ligation and transection of the vessels can be carried out using titanium or Weck clips and using scissors or a thermal device such as LigaSure™ or Harmonic scalpel.

The magnification offered by the laparoscopic approach assists in performing a lymphatic-sparing approach where the small translucent vessels are carefully dissected off the artery and vein and spared [25, 26]. This approach may limit hydrocele formation postoperatively (Figure 119.7). The injection of methylene blue into the subdartos tissue around the cord has been shown to help identify and isolate the lymphatics with good results [27]. In a series of 25 patients by Capolicchio et al. they had no postoperative hydroceles with a mean follow-up of 13 months. In addition, the use of a laparoscopic Doppler probe may be useful in sparing the testicular artery. This method may increase the recurrence of the varicocele but helps to improve semen parameters [9, 24].

The patient is then taken out of Trendelenburg and the surgical field is inspected. A laparoscopic aspirator may be used to suction any blood or irrigant that has pooled; however, we do not routinely open the device as its use is rarely necessary. The trocars are then removed under direct vision. With the use of 5 mm trocars it may not be necessary to close the fascia; however, it is our practice to routinely close the fascia with a 2-0 absorbable suture in figure-of-eight using a direct vision and groove director. The skin is closed with a 5-0 monofilament suture in a subcuticular fashion and Steri-Strips with collodion are applied (Figure 119.8). A weight-based dose of local anesthetic is injected at the end of the case.

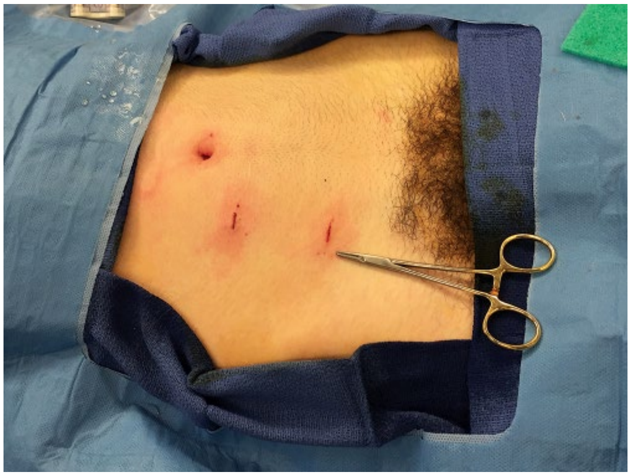

**Figure 119.8** The skin is closed with a 5-0 monofilament suture in a subcuticular fashion.

## Complications

Early complications include injury to adjacent organs, bleeding from insufficient spermatic vessel ligation, failure to ensure adequate hemostasis or injury to the inferior epigastric vessels. These complications are rare when using direct visualization and magnification. There is risk of bowel injury either through blind trocar placement, use of cautery and coupling, or through sharp dissection. By choosing plastic trocars and Trendelenburg these risks can be minimized. In a randomized controlled study of 654 pediatric patients comparing laparoscopic versus open varicocelectomy, Podkamenev et al. reported decreased testicular or scrotal edema rates of 3.9% versus 13.1%, wound complication rates of 0.23% versus 7.73%, and shorter operative times with 15 versus 26 minutes, respectively; however, there was no statistical difference between hydrocele rates of 0.23% versus 1.2% or recurrence rates of 1.84% versus 1.36% [28].

Late complications include hydroceles and recurrences. When comparing microsurgical, Palomo, embolization, inguinal, and laparoscopic approaches, postoperative hydroceles are reported as 0–1.6%, 4.6–9%, 0%, 4.3–17.5%, and 1.7–12.7%, while recurrences rates are 0.7–15.2%, 7.3–15.5%, 1.9–9.3%, 3.35–17%, and 4–26.5%, respectively [29, 30]. Hydroceles have been reported to occur on average up to 2 years (range 0.3–7.5 years) following the procedure [29]. Although hydroceles may occur following a mass ligation of the cord, Feber and Kass, reporting on adolescents undergoing an open Palomo approach, found that only 17% of the hydroceles required subsequent surgery [31]. We have found great success in managing recurrent varicocele using embolization. In our series of 60 patients undergoing salvage embolization, the presence of inguinal and retroperitoneal collaterals were significant independent prognosticators for recurrence and they were managed easily with this technique [32].

Borruto et al. in 2010 reported no difference between postoperative hydrocele or recurrence rates in a meta-analysis of 11 studies examining laparoscopic compared to open varicocelectomy [16]. In a large multicenter study of 1036 adolescents who underwent varicocelectomy either by open (39%), laparoscopic (51%), or percutaneous embolization (9.8%) Lurvey et al. reported significantly higher retreatment rates with embolization (1.5%, 3.4%, and 9.9%, respectively) while there was no statistical difference in hydrocele formation (4.9%, 8.1%, and 5%, respectively) [33]. Interestingly, they did note a higher hydrocele formation in younger patients with each year increase of age: there was 14% reduction in hydrocele formation with 1–5 years of follow-up. This finding may give more credence to observation in younger patients found to have an incident asymptomatic varicoceles.

## Outcomes

The goal of varicocelectomy in the pediatric population is to preserve future fertility while at the same time preventing morbidity. Direct evidence for preserving future fertility in pediatric population is lacking but many studies in the adult population demonstrate successful pregnancies in subfertile males. Pregnancy rates vary from 33.8–51.5% in a microsurgical subinguinal approach to 33–36% with a traditional Palomo approach to 13.1–40% utilizing laparoscopy, which is an improvement considering most adult studies involve treatment in subfertile males [3, 29].

Several studies have compared laparoscopic to open variocelectomy. Early comparisons demonstrated no superiority with respect to hospital stay, analgesic requirements, return to work, or operative times; however, over the past decade this has improved with refinement of the laparoscopic procedure [34]. In today's medical environment it is important to be cost-conscious. Al-Kandari et al. estimated costs of open, laparoscopic, and microscopic varicocelectomy at US$1800, US$2700, and US$2400 for unilateral and US$2100, US$3600, and US$3000 in bilateral procedures, respectively [35]. Robotic varicocelectomies have been reported to have outcomes similar to those of laparoscopy but have longer operative times when compared to laparoscopy (112 vs. 73 minutes) and significantly higher costs (US$15 000 vs. $8600) [36].

Recent studies have examined the different techniques utilized when performing a laparoscopic varicolectomy such as complete ligation versus lymphatic and/or testicular artery-sparing. Barroso et al. found no statistical difference in hydrocele or recurrence rates between the traditional open Palomo compared to laparoscopic approaches (9.7% vs. 6.9% and 2.9% vs. 4.4%, respectively) but reduced the hydrocele rate to 3.2% by sparing the testicular artery [37]. Kang et al. compared single-site laparoscopic variocelectomy with artery/lymphatic-sparing versus complete ligation of the cord and found a 0% hydrocele rate with a 2.9% recurrence rate in the sparing cohort while the complete ligation cohort experienced a 5.7% hydrocele rate and similar recurrence rate. Also, at three months follow-up there was improvement in both groups' semen parameters, with no difference between the groups [24]. Kim et al. compared complete ligation versus internal spermatic cord artery-sparing ligation and found a 5% versus 22% recurrence rate, respectively, but no hydrocele formation in the artery-sparing cohort compared to 4.7% in the complete ligation group [9]. When comparing specifically lymphatic-sparing to complete ligation Rizkala et al. noted a 4.5% hydrocele rate in the lymphatic-sparing laparoscopic approach versus 43% in the complete ligation group, with hydroceles forming much later in the complete ligation group (37 vs. 16 months) [26]. When the artery was not preserved in the lymphatic-sparing group the recurrence rate decreased from 6% to 1.3%. All of these studies showed adequate testicular catch-up growth regardless of the method used, and no hypotrophy, while reoperative rates for the hydroceles ranged from 0% to 31% and all recurrences were successfully managed with embolization. It is important to note that Zampieri et al. was able to demonstrate improvement of multiple semen parameters when the testicular artery was spared compared to it being ligated; however, in an adult population this did not necessarily translate to improved paternity [8, 35, 37, 38].

It has been noted that catch-up growth of the testicle improves with treatment as compared to observation, and that semen parameters, including total motility count, also improve with treatment [2, 38–41]. The degree of these improvements tends to parallel the grade of varicoceles; hence, physicians advocate for treatment of high-grade adolescent varicoceles in the absence of direct evidence that it improves fertility.

A more recent finding is that DNA fragmentation has been noted to lead to sperm damage and decreased pregnancy rates and has been found in patients with varicoceles [42]. A recent meta-analysis of adult patients with subfertility by Marmar et al. demonstrated an increased odds ratio of spontaneous pregnancy after varicocelectomy and other recent investigations have attributed this to a decrease in DNA fragmentation associated with a varicocelectomy [42, 43]. Lacerda et al. investigated DNA fragmentation in 21 adolescents between the ages of 14 and 19 and found improvements following varicocelectomy. In the future, DNA fragmentation may serve as a marker for those patients who could benefit from earlier intervention [44].

## Follow-up

Our patients return to the office 10–14 days following surgery to assess the trocar sites for good wound healing, signs of infection, hernias, etc. They follow-up again approximately 4–6 months later with a scrotal ultrasound to assess for recurrent varicoceles, hydrocele formation, and measurement of catch-up growth. If the patient had a preoperative semen analysis, we then request a follow-up semen analysis at this visit. Our last visit is scheduled at 2 years to assess the same parameters. If there is improvement in semen parameters, good catch-up growth, no hydrocele, and no recurrent varicocele we will have the patient return as needed.

## Conclusion

The adolescent varicocelectomy remains an evolving area of investigation. Many studies address issues of testicular growth, changes in semen parameters, complications, and timing of the procedure; however, without randomized prospective studies comparing treatment to observation, specifically examining paternity rates, there is a quintessential piece of data missing. This fact, combined with the current body of knowledge comprising varying degrees of evidence and very few being grade A, makes the issue of whether the benefits of varicocelectomy outweighs the harms a complex and unanswered question. However, when specifically examining the option of laparoscopy for treatment of the adolescent varicocele several conclusions can be made.

The laparoscopic approach to treating the adolescent varicocele with current technology and methods may rival or exceed success and complication rates when compared to the microsurgical approach and the traditional open Palomo procedure. Sparing the lymphatics reduces the risk of subsequent hydrocele formation; however, the need for intervention of these hydroceles is low and may bring into question the need for a lymphatic-sparing approach. In addition, we understand that sparing the artery will lead to higher recurrence rates but also to improvements in semen parameters. Last, with regard to catch-up growth, the ipsilateral testicle does improve with treatment; however, adolescents have asymmetrical growth during puberty and hence may warrant a longer period of observation.

In conclusion, laparoscopic varicocelectomy in the hands of an experienced surgeon can offer highly effective results with minimal complications. Future investigation should include randomized controlled studies of treatment versus observation and lab studies, such as DNA fragmentation, may in the future offer us further ability to identify those patients who would benefit from early intervention.

# Part 7 Laparoscopy and Robotics: LESS and NOTES

## 120

## Laparoendoscopic Single-site Surgery: Ports, Access, and Instrumentation

*Noah E. Canvasser & Jeffrey A. Cadeddu*

*Department of Urology, University of Texas Southwestern Medical Center, Dallas, TX, USA*

### Introduction

Since the first laparoscopic nephrectomy by Dr. Clayman in 1991 [1], advancements in minimally invasive surgery have led a push for even less invasive techniques. With reported benefits of improved cosmesis and less pain, Rane et al. presented the first single laparoscopic port procedure, called SLiPP, at the 2007 World Congress of Endourology [2]. Growing interest, varied surgical approaches, and differing language culminated in the formation of the Laparoendoscopic Single-Site Surgery Consortium for Assessment and Research (LESSCAR). A white paper was published in 2008 defining laparoendoscopic single-site (LESS) surgery as the umbrella term of this new technique [3]. Subsequent advancements in robotic surgery led to Kaouk et al. publishing the first urologic robotic LESS (R-LESS) series in 2009, reporting improved suturing and dissection compared to standard LESS surgery [4].

With increased adoption of both LESS and R-LESS over the following years, technology has broadened potential applications by improving ports, instrumentation, and optics. Herein, we discuss currently available products designed for LESS and R-LESS approaches.

### Ports

With the acceptance of LESS and R-LESS techniques, many new ports came to market. An analysis during the early adoption phase of LESS surgery (2007–2010) evaluated platform selection [5]. Of 1076 cases, 77% were performed with a single port (i.e. one skin and one fascial incision), while the remaining 23% were single-site with multiple trocars (i.e. one skin and multiple fascial incisions). The most popular single-port device at that time was homemade (46%), followed by TriPort™/QuadPort™ (29%), SILS™ Port (8%), GelPort®/GelPOINT® (7%), and X-Cone™/Endocone™ (5%). Although R-LESS was chosen in only 13% of cases, temporal trends noted increased utilization with a concurrent decrease in standard LESS surgery, which might explain the current selection of devices available [5]. This section focuses on currently available ports, and highlights described utilization for each in the literature.

#### Single-incision multiport

Single-incision multiport LESS surgery describes a single-skin incision with multiple standard low-profile laparoscopic trocars in separate fascial incisions (Figure 120.1a). Benefits include access to readily available products with potential downsides of external clashing. In 2007, Raman et al. described using this technique in a pig model, with subsequent successful completion in three humans [6]. Additional reports since that time have described this technique with transperitoneal LESS donor nephrectomy [7].

#### Homemade

Prior to the introduction of dedicated single-port devices, many clinicians created their own LESS ports. A popular method uses an Alexis® retractor and a surgical glove. Ports are placed through the fingers of the glove and secured with suture (Figure 120.1b) [8]. Benefits to using this system include flexibility in port placement, as well as the ability to use standard laparoscopic instruments given the potential wide range of motion [8]. Issues utilizing this type of system include lack of rigidity and port stability, as well as tearing of the glove requiring the need to stop the operation and redo the port [8–10].

Reports describing the glove technique have included transperitoneal nephrectomy, partial nephrectomy, nephroureterectomy, adrenalectomy, partial cystectomy, ureterectomy, varicocelectomy, cyst decortication, ureterolithotomy, prostatic enucleation, and bladder rupture repair [8, 9]. This technique has also been utilized for R-LESS cases, including transperitoneal nephrectomy, partial nephrectomy, adrenalectomy, and nephroureterectomy [8, 10].

### TriPort+/TriPort15™/QuadPort+™ (Advanced Surgical Concepts, Bray, Ireland)

The first LESS port on the market, originally called the R-Port™ and subsequently the TriPort, was used in the first reported LESS nephrectomy [2] and the first R-LESS series [4]. Advanced Surgical Concepts now has three current configurations utilizing this technology: TriPort+, TriPort15, and QuadPort+. Models are currently distributed by Olympus (Tokyo, Japan). Each port has an internal anchoring ring that is placed through a Hasson incision with a blunt trocar and secures the device to the parietal peritoneum. An outer ring cinches down over a plastic sleeve to create a tight seal on the abdominal wall. The excess sleeve is excised prior to securing the port cap. The ports are built into the cap, and allow the passage of curved instruments due to their flexibility.

Both TriPort + and TriPort15 models are used with fascial incisions 12–25 mm and can accommodate abdominal walls up to 10 cm thick. They have two insufflation and/or ventilation ports, with the main difference being the working channels. The TriPort + has three 5 mm ports and one 5–10 mm port (Figure 120.1c) and the TriPort15 has two 5 mm ports and one 5–15 mm port (Figure 120.1d).

With the ability to accommodate the same abdominal wall thickness of 10 cm, the QuadPort + is for fascial incisions between 25 and 60 mm. It has two 5 mm ports, two 5–10 mm ports, and one 5–15 mm port, as well as two insufflation and/or ventilation ports (Figure 120.1e).

TriPort has shown broad utilization in the literature. In pediatric urology, it has been used for ochidopexy [11], varicocelectomy [12], simple nephrectomy [11, 13], and pyeloplasty [11, 13].

For adult transperitoneal LESS surgery, reports include partial nephrectomy [14, 15], radical nephrectomy [16], donor nephrectomy [17], adrenalectomy [18], vesicovaginal fistula repair [19], bladder diverticulectomy [20], and pyeloplasty [12]. Extraperitoneal LESS usage with TriPort has included cyst decortication [21], adrenalectomy [22], and radical prostatectomy [23]. More limited reports depict use of the TriPort to transvesically remove mesh [24, 25] and perform a bladder diverticulectomy [26].

Early R-LESS reports describe placing one robotic arm alongside the TriPort, but through the same skin incision, to limit instrument clashing. This technique has been utilized for radical prostatectomy, pyeloplasty, radical nephrectomy, and partial nephrectomy [4, 27].

### SILS port (Covidien, Dublin, Ireland)

The SILS port is a flexible foam port that is placed via Hasson technique through an approximate 2.0 cm fascial incision (Figure 120.1f). The low-profile design can mold to the incision tightly to limit gas leakage, but due to its relatively fixed size cannot accept a large range of fasical incision sizes or abdominal wall thicknesses. The three different models (SILSPT5TA, SILSPT12TA, and SILSPT15TA) each accommodate three trocars at a time, with the first two being 5 mm, and the last trocar either 5 mm, 5–12 mm, or 5–15 mm, respectively. There is also a separate insufflation/ventilation port, and one of the 5 mm ports has a side hole for additional insufflation/ventilation if needed.

Reports have described using the SILS port for pediatric cases [11], including simple nephrectomies [28]. In the adult literature, the SILS port has been utilized for transperitoneal LESS donor nephrectomy [7], varicocelectomy [29], and adrenalectomy [30], as well as retroperitoneal LESS adrenalectomy [31].

Because of its low-profile design and to prevent external clashing of instruments, adaptations to use the SILS port for R-LESS involve adjacently placed robotic ports through the same skin incision, essentially robotic single-site surgery [32]. This has been completed in patients undergoing robotic prostatectomy [33] and in select radical nephrectomy cases [34].

### GelPOINT/GelPOINT Mini (Applied Medical, Rancho Santa Margarita, CA, USA)

This system is based on an Alexis® wound retractor and is an evolution of the GelPort system. The device comes in two sizes, GelPOINT (incisions 1.5–7.0 cm, Figure 120.1 g) and GelPOINT Mini (incisions 1.5–3.0 cm, Figure 120.1 h). The retractor is placed through a Hasson incision and cinched to the abdominal wall. A GelSeal® cap is secured to the retractor, forming a tight seal and preventing gas leakage. Both systems incorporate three 5–10 mm sleeves and one 5–12 mm sleeve. The sleeves, which function as ports, are placed through the cap in a customizable configuration. In addition, two insufflation and/or venting ports are available on the cap. Benefits of these systems include the ability to move the ports in a number of configurations to prevent external and internal clashing. This has made this system ideal for R-LESS adoption, and is currently in use at the author’s institution.

To perform, robotic 5 mm flared trocars are predocked onto the robot arms and clutched through the sleeves.

Pediatric LESS reports using GelPOINT include transperitoneal nephrectomy, nephroureterectomy, partial nephrectomy, renal cyst decortication, gonadectomy, Malone antegrade continence enema, calyceal diverticulectomy, and ovarian detorsion with cystectomy [35]. Pediatric retroperitoneal LESS nephrectomy has also been reported [36].

Adult LESS procedures include transperitoneal nephrectomy [37] and donor nephrectomy [7, 38–41], and retroperitoneal nephrectomy [42], partial nephrectomy [43], and donor nephrectomy [44].

R-LESS procedures have included pyeloplasty [45], partial nephrectomy [45], and radical nephrectomy [34, 45]. In addition, GelPOINT Mini was used to perform the first R-LESS perineal prostatectomy [46].

## OCTO™ Port V2 (DalimSurgnet, Seoul, Korea)

The OCTO Port V2 is a two-piece device, consisting of a wound retractor and a port cap (Figure 120.1i). The wound retractor comes in three sizes: 1.5–3.0 cm, 3.5–5.0 cm, and a deeper 3.5–5.0 cm for thicker abdominal walls. An inner ring is placed through a Hasson incision, and secured by stretching the externalized silicone around the external ring. The port cap comes with either three (one 5 mm and two 5–12 mm) or four (two 5 mm and two 5–12 mm) built-in ports. In addition, each four-port cap can be in one of two configurations: (i) 5 mm ports on opposite sides and (ii) 5 mm ports on the same side, giving multiple different options depending on surgeon preference and the operation performed. The port caps are made of silicone, making them flexible during laparoscopy and allowing passage of curved instruments. After securing to the wound retractor, the port cap can rotate 360°, allowing for versatility in instrument position. There are also two smoke filtering systems and a separate insufflation port.

Notable OCTO Port use in the literature includes transperitoneal LESS radical nephrectomies in humans [47] and partial nephrectomies in a porcine model [48].

## X-Cone, Endocone, S-Port™ (Karl Storz, Tuttlingen, Germany)

The X-Cone is a reusable single-port device that consists of two metal halves that secure together to form a 2.5 cm cone (Figure 120.1j). A fascial incision of approximately 2.0 cm is used, and the two halves are inserted separately before securing in place. The silicone sealing assembly with built-in ports is secured on top of the cone. The port configuration is four 5 mm ports and one 5–12 mm port. There are two additional adapters for insufflation and/or venting.

The Endocone is a 3.4 cm multilumen reusable port with six 3–5 mm channels, one 5–12 mm channel, and one 5–15 mm channel (Figure 120.1k). It has a separate insufflation port, and is placed through a 3.0–5.0 cm fascial incision using the Hasson technique.

The S-Port consists of single-use wound retractors and an attachment cap that has an insufflation port. Once secured to the wound retractor, either the X-Cone or Endocone seal cap can be secured on top for variations in port placement.

Reports in pediatric urology have included transperitoneal LESS nephroureterectomy [49], nephrectomy, and orchidopexy [50].

Reports in adult urology have described using the X-Cone to perform transperitoneal LESS staging lymphadenectomy in patients with high-risk prostate cancer [51], varicocelectomy [52], radical nephrectomy, partial nephrectomy, pyeloplasty, and renal cyst ablation [53].

Greco et al. utilized the Endocone to perform LESS transperitoneal radical nephrectomy in 33 patients [54].

## Single-Site™ port (Intuitive Surgical Inc., Sunnyvale, CA, USA)

The Single-Site port is the first platform designed specifically for R-LESS with the da Vinci® Si Surgical System (Figure 120.1l). The flexible port is placed through a 1.5 cm fascial incision and has access for the 8.5 mm robotic endoscope, two 5 mm curved robotic cannulae, a 5–10 mm assistant port, and an insufflation port. The curved cannulae are designed to recreate triangulation and are used specifically with Intuitive semirigid instruments (described later).

R-LESS reports using this device have included pyeloplasty [55], radical nephrectomy [56], and partial nephrectomy [57].

## Comparison

The decision on which port or access system to use depends on multiple factors: whether the procedure is laparoscopic or robotic, trans- or extraperitoneal, pediatric or adult, and upper or lower tract, among others. However, multiple studies have attempted to compare the various devices in training simulation. Two independent investigators noted no benefit of access devices over single-incision multiport setups [58], including less instrument strain and shorter performance time with the latter [59]. Focusing on just the advanced device platforms, studies have shown the GelPOINT [60, 61] and the SILS port [61] to be the most consistent with regards to simulation completion.

For R-LESS, White et al. compared SILS port, GelPOINT, and TriPort, and preferred SILS port with adjacent robotic trocars for its durability, ability to exchange trocar sizes, and maximal range of motion [32, 34]. Ultimately, the port or access device used is a personal choice and we recommend trialing various models to determine what works best.

## Access

### Transperitoneal

Transperitoneal LESS access is typically obtained at the umbilicus to hide the surgical scar, although any abdominal entry site could be used based on patient or surgical factors. After making a skin incision, subcutaneous tissue is dissected to expose rectus fascia. If performing single-incision surgery, the fascia is typically retracted with Kocher clamps and a Veress needle placed to insufflate the abdomen [6]. Retractors are often used to stretch the skin in order to place the ports at the extent of the fascia. If performing single-port surgery, the Hasson technique is used to gain intraperitoneal access. After making a fascial incision of appropriate length based on the port chosen, the peritoneal cavity is accessed by sharply dividing preperitoneal fat and peritoneum. Before inserting the port, we recommend performing a finger sweep to ensure no adhesions are present where the port will be secured.

### Extraperitoneal

Both infra-umbilical and retroperitoneal LESS have been described and both utilize similar access techniques. For the former, an infra-umbilical skin incision of appropriate length, depending on the port to be used, is made and subcutaneous tissues are dissected, exposing anterior rectus fascia. An incision is made in the fascia and the rectus muscle is separated, exposing posterior rectus sheath. A finger is used to bluntly sweep anterior to the posterior rectus sheath in order to create a plane in the space of Retzius. A balloon dilating port can be used to develop this space prior to inserting the LESS port [23].

Retroperitoneal LESS surgery is typically performed off the 12th rib in the midaxillary line, although more inferior incisions have been described [22, 42, 43]. After dividing subcutaneous tissues, a Kelly clamp can be used to bluntly poke through lumbodorsal fascia into the retroperitoneal space. By inserting a finger into the space, a plane can be created, palpating the psoas muscle posteriorly and the lower pole of the kidney anteriorly. A balloon dilating port is again used under visualize guidance to enlarge this space, during which the psoas muscle should be kept horizontal to maintain orientation. Prior to inserting the LESS port, the fascial incision is often elongated, depending on the port used [42].

## Instrumentation

With adoption of LESS came advancements in instrumentation due to the loss of standard laparoscopic triangulation. Although any laparoscopic instrument could technically be used for LESS approaches [62], both prebent and articulating instruments are more frequently utilized [5]. Instruments sometimes require “chopstick” laparoscopy, where they cross at the fascial level, and the surgeon’s right and left hands control the intracorporeal left and right tip, respectively. In the following section we summarize currently available LESS and R-LESS instrumentation. Although literature regarding these instruments is less often highlighted, we cite the use when possible.

### HiQ LS handles and instruments (Olympus)

HiQ LS handles and instruments are 5 mm reusable instruments with a proximal curve to prevent external clashing, as well as distal double curves to restore triangulation without the surgeon having to cross instruments (Figure 120.2a). The rigid curves of these instruments limits their use to flexible ports such as TriPort+/TriPort15/QuadPort+. Graspers include Johann (atraumatic fenestrated), clinching (atraumatic), and a long multipurpose (atraumatic). Dissectors include a short Maryland, fine Maryland, and a right-angle Maryland. Electrocautery devices include a monopolar hook and Metzenbaum scissors, although both the monopolar handle and the deactivatable ratchet handle can be used with all instruments.

These instruments have been utilized for LESS vesicovaginal fistula repair [19], as well as donor nephrectomy [7].

### SILS hand instruments (Covidien)

This line of 5 mm single-use instruments can be used in a standard or “chopstick,” method. To recreate triangulation, the distal ends of the instruments articulate up to 85° in all directions by bending the handle externally. They also can rotate 360° (Figure 120.2b). Their straight design with articulated end allows these instruments to be used in any port. Instruments include a dissector, shears, and a hook, all with monopolar cautery, as well as a grasper.

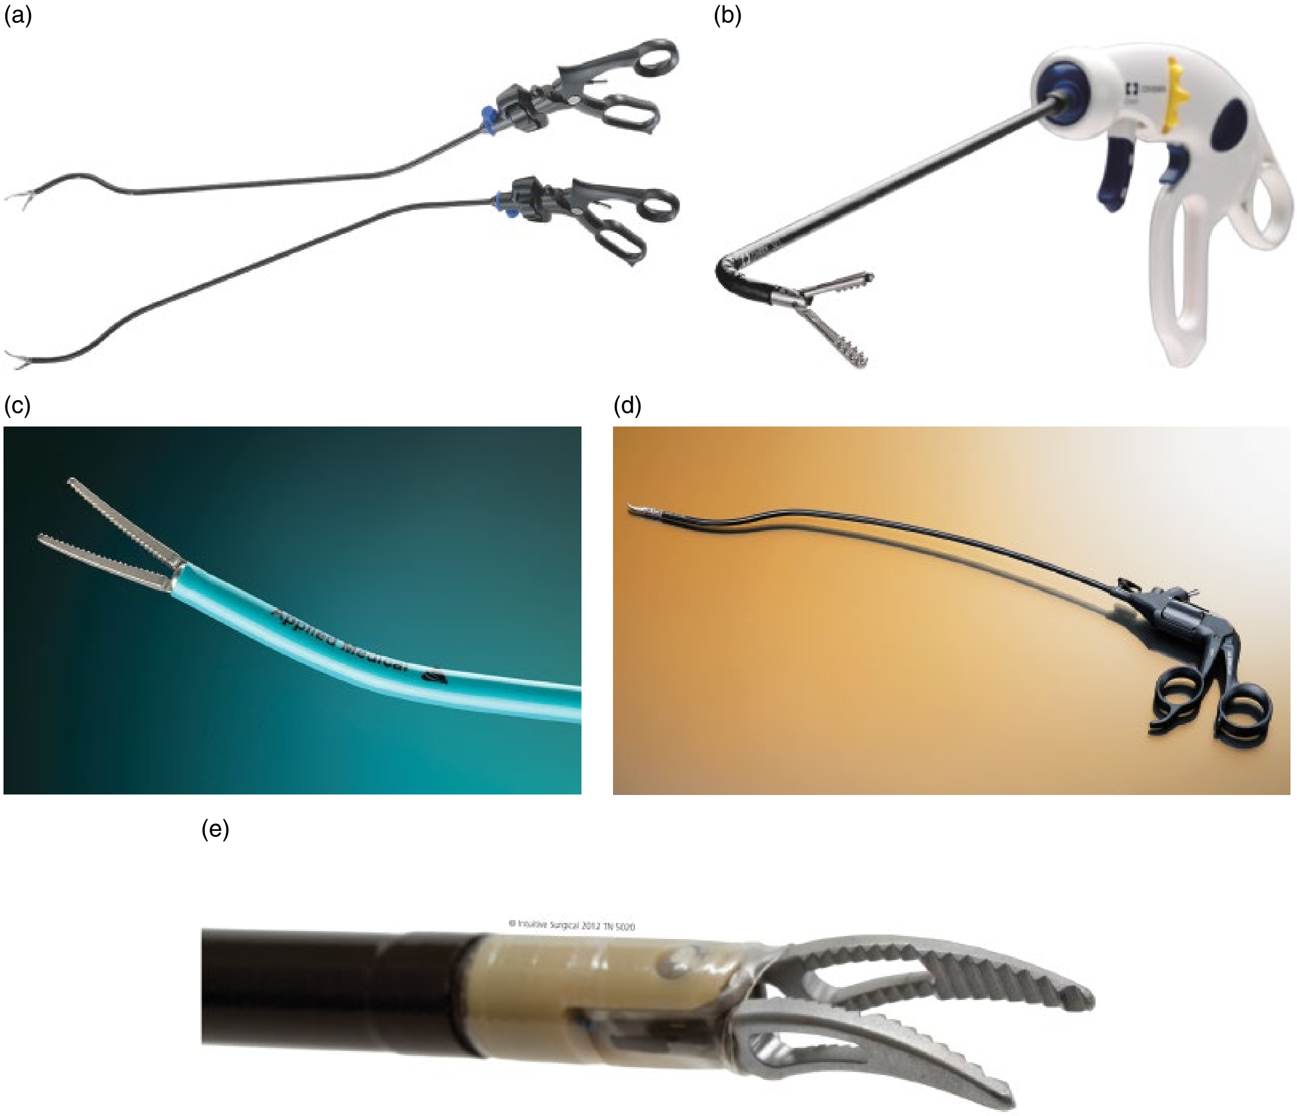

**Figure 120.2** Currently available laparoendoscopic single-site (LESS) instrumentation. (a) HiQ LS handles and instruments. (b) SILS hand instrument. (c) Epix inline angled dissector. (d) Rotatip CUSCHIERI D-CON. (e) Semirigid Maryland bipolar. *Sources:* (a) Olympus America Inc. Reproduced with permission of Olympus. (b) Medtronic, New Haven, USA. Reproduced with permission of Intuitive Surgical Inc.

### Epix® inline angled dissector (Applied Medical, Rancho Santa Margarita, CA, USA)

Applied Medical has a line of 5 mm single-use laparoscopic instrumentation called Epix. Of the instruments, the angled dissector is the only one with a distal angle of 20°, which helps to facilitate triangulation during LESS surgery (Figure 120.2c). Although it is a fixed angle, the slight degree allows it to still be used in rigid ports similar to the GelPOINT system.

This instrument was used by Cherian et al. to perform retroperitoneal LESS nephrectomy [63].

### Rotatip® instruments (Karl Storz)

These 5 mm reusable curved instruments can be dismantled into three parts: handle, outer sheath, and working insert, and each insert can rotate independently of the outer sheath. There are four different sheath curves available, depending on the application: CARUS, CUSCHIERI O-CON, CUSCHIERI D-CON I, and LEROY. The CARUS sheath has a straight outer sheath and a double curved distal sheath to recreate triangulation. With the jaw offset at 45° to the axis of the outer sheath, the double distal curve allows a good view of the instrument. In contrast, the CUSCHIERI O-CON sheath has a straight outer sheath, and a single distal sheath curve. The CUSCHIERI D-CON I has a single curved outer sheath along with a double curved inner sheath (similar to the CARUS), to recreate triangulation and limit external clashing (Figure 120.2d). Lastly, the LEROY has a double curved outer sheath and a similar double curved inner sheath, to minimize external clashing and maximize triangulation. The handle and distal end of the LEROY sheath form a straight line, so movements can be more intuitive. Each sheath comes in Kelly forceps, atraumatic grasping forceps, and Metzebaum scissors.

### Semirigid instruments (Intuitive Surgical Inc.)

This selection of 5 mm R-LESS instruments are designed specifically for use in the curved cannulae of the Single-Site port. The cannulae cross in the midline similar to the "chopstick," method, but because the da Vinci Si Surgical System reconfigures the right and left hands to control opposite instruments, the result is more natural. Most of these instruments have a fixed wrist, unlike standard da Vinci instrumentation. The lone exception is the wristed needle driver, which can bend up to 45°. Other instruments include a cadiere forceps, crocodile grasper, fundus grasper, Maryland dissector, Maryland bipolar (Figure 120.2e), fenestrated bipolar, monopolar hook cautery, curved scissors, curved needle driver (not wristed), Hem-o-lok® clip applier, and suction irrigator. This system is currently only available with da Vinci Si Surgical System.

As before, these instruments have been used in pyeloplasty [55], radical nephrectomy [56], and partial nephrectomy [57].

### Comparison

A 2010 study by Stolzenburg and colleagues compared straight instruments in a standard laparoscopic port configuration to pre-bent and articulating instruments in a single-port dry model and porcine nephrectomy model. They noted no significant difference between the standard laparoscopic and pre-bent instruments, but significantly slower times with the articulating instruments [64]. As with ports and access devices, we recommend trialing multiple instruments to determine what works best.

## Camera/lenses

Given the tight external working space with LESS surgery, camera adaptations to improve movement and visualization have been developed. It is important to note that articulating laparoscopes have a digital chip in their tip, and are covered with a plastic casing that can degrade over time [65].

We describe three different cameras that have been designed specifically for LESS.

### ENDOEYE FLEX (Olympus)

The ENDOEYE FLEX is a 5 mm high-definition laparoscope that can articulate up to 100° in all directions and rotate 360° degrees (Figure 120.3a). It has a digital chip at the distal end, with built-in camera and light cord. The design allows maneuverability to minimize external clashing while still obtaining appropriate viewing angles.

### IDEAL EYES HD (Stryker, Kalamazoo, MI, USA)

The IDEAL EYES HD is a 5 mm high-definition laparascope that can articulate 100° in all directions and rotate 360° degrees. It has a digital chip at the distal end, the handle is angled 15° for improved ergonomics, and the camera and light are in an integrated cable.

### EndoCAMeleon (Karl Storz)

The EndoCAMeleon is a 10 mm telescope with a viewing angle that adjusts from 0 to 120° by rotating a knob near the light port (Figure 120.3b). The digital chip in the end rotates within the scope, so there is no plastic casing that might degrade [65]. Therefore, it is potentially more durable.

## Other products

### AirSeal® (CONMED, Utica, NY, USA)

The AirSeal system consists of an intelligent flow system (iFS), along with proprietary tubing and ports. This unique device can operate in three different modes: AirSeal, smoke evacuation, and continuous insufflation. In AirSeal mode, the port recirculates $CO_2$ with high-pressure nozzles in the cannula to create an air barrier and stable pneumoperitoneum without valves, regardless of the amount of suction used. Continuous air circulation also constantly evacuates intra-abdominal smoke, which can be a problem with LESS and R-LESS due to the close proximity of working instruments and the camera. Access ports are available in 5 mm, 8 mm, and 12 mm

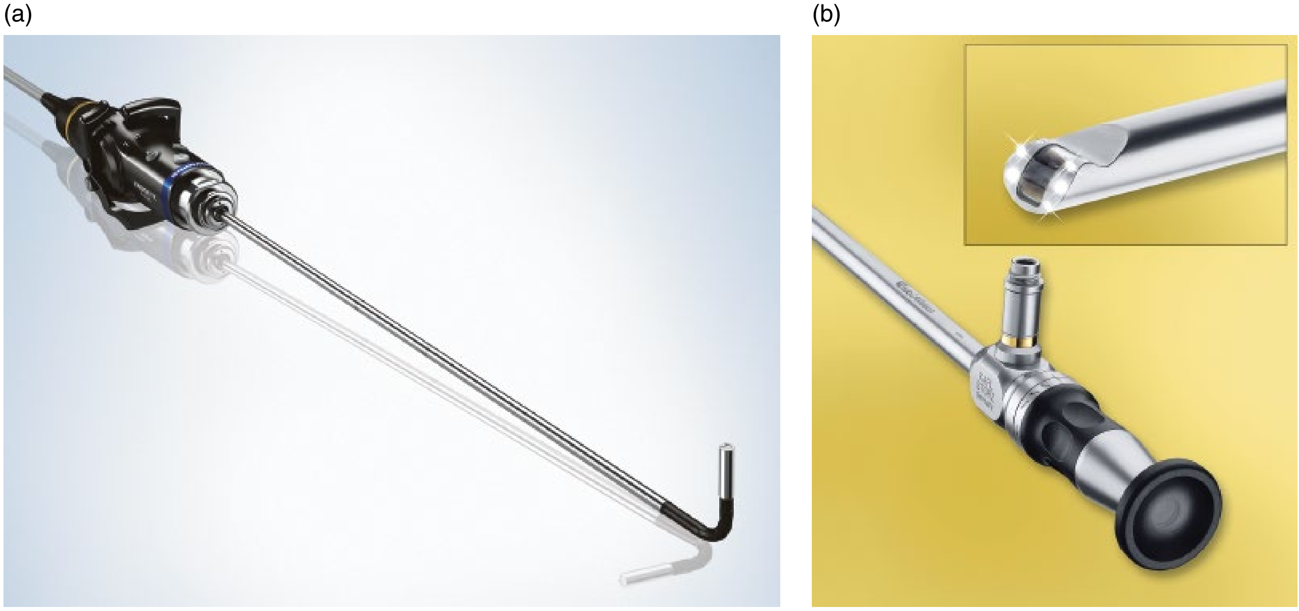

**Figure 120.3** Currently available laparoendoscopic single-site (LESS) cameras/lenses. (a) ENDOEYE FLEX. (b) EndoCAMeleon. Sources: (a) Olympus America Inc. Reproduced with permission of Olympus. (b) Karl Storz Endoscopy-America, Inc., California, USA. Reproduced with permission of Karl Storz Endoscopy-America, Inc.

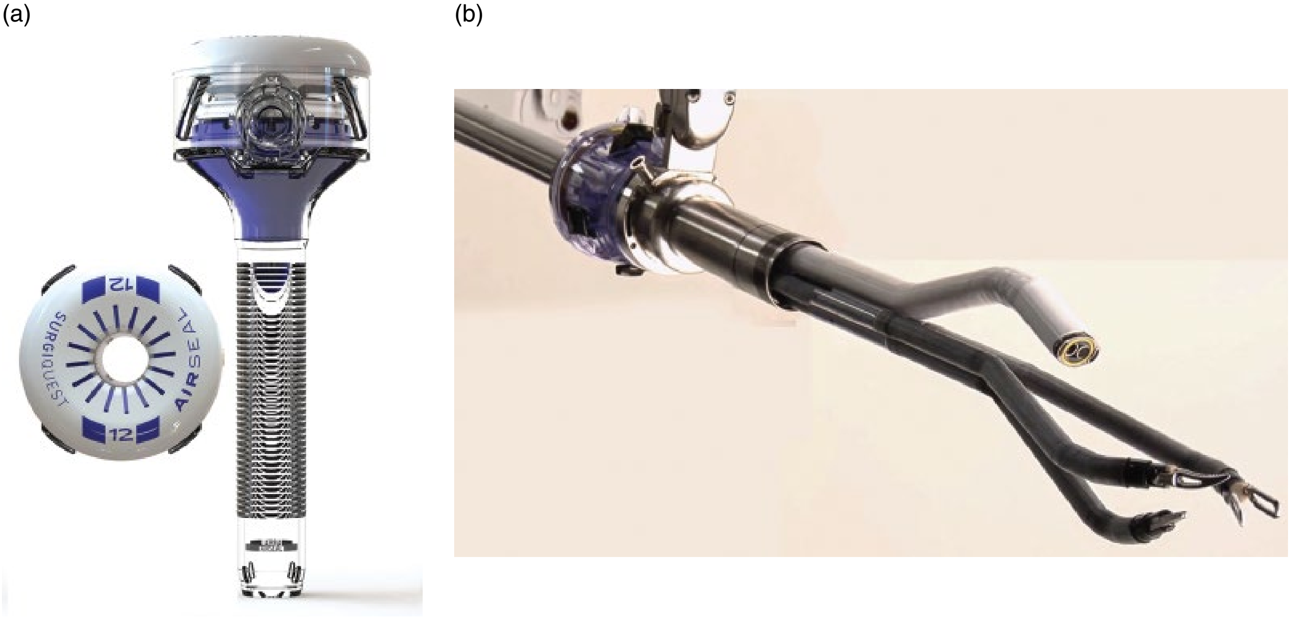

**Figure 120.4** Other laparoendoscopic single-site (LESS) products. (a) AirSeal. (b) da Vinci Sp Surgical System. *Source:* (a) CONMED Corporation, New York, USA. Reproduced with permission of CONMED Corporation. (b) Intuitive Surgical Inc., California, USA. Reproduced with permission of Intuitive Surgical Inc.

sizes (Figure 120.4a). Because of the need for specialized ports, AirSeal ports are only compatible with devices similar to the SILS port and GelPOINT. In smoke evacuation mode, proprietary dual-lumen insufflation tubing is connected to the iFS and two conventional ports. This can be used with any LESS port setup as long as two access points are available. For continuous insufflation mode, standard laparoscopic insufflation tubing can be connected from the iFS to a single conventional port to provide high-flow insufflation.

## Other systems

### da Vinci SP Surgical System (Intuitive Surgical Inc.)

This R-LESS system is not yet on the market, although it received US Food and Drug Administration (FDA) 510 k clearance in April 2014. It is designed to be used with the da Vinci Xi Surgical System. The SP platform is a separate patient-side cart which uses the Xi surgeon console and vision cart with a new software and foot pedal to allow for new control modes.

The port is a 2.5 cm cannula, with a 3D articulating high-definition 6 mm camera and three fully articulating 6 mm instruments (Figure 120.4b). Each instrument has EndoWrist® at the distal joint, in comparison to the semi-rigid single-site surgery instruments, as well as a proximal articulating joint to allow for triangulation [66].

Kaouk et al. performed 11 radical prostatectomies and 8 radical nephrectomies utilizing a previous platform, SP999 [67]. The newer platform is model SP1098.

See accompanying Video 120.1.

## Introduction

Since 1991, when the first laparoscopic nephrectomy was reported, laparoscopy has flourished in urology for the treatment of both benign and malignant conditions. Techniques and instrumentation have evolved to address more complex cases and pathology. New trocars, optics, instruments, and robotic devices have all been developed in a collective effort to improve efficacy, minimize patient morbidity, and reach for superior cosmetic results.

Laparoendoscopic single-site (LESS) surgery is one example of how new technology and new techniques have converged to allow for the performance of complex surgery through fewer incisions. In a short time span, nearly the entire gamut of urologic procedures has been performed via a LESS approach [1, 2]. Moreover, the diffusion of LESS has been fairly rapid across the globe. The goal of LESS surgery is to provide equivalent surgical outcomes with improved cosmetic results. Ongoing research is aimed at clarifying what, if any, perioperative or convalescence-related benefits may be offered by minimizing the number of incisions and cumulative incision length used compared to conventional laparoscopy [3]. In addition, the role of robotics in LESS surgeries continues to be explored as a viable modality, the hope being that the shorter learning curve associated with robotic assistance may allow dissemination of LESS surgery to a greater number of patients.

Of the cases reported in the literature to date, the largest experience of urologic LESS surgery has been in the upper urinary tract, specifically renal procedures [1]. Upper tract urologic LESS surgery consists of both extirpative and reconstructive procedures of the kidneys, adrenal glands, and ureters. There is potential for high surgical volume of LESS procedures for renal and adrenal pathology, but challenges remain to its diffusion into widespread practice [4].

Although LESS surgery is a direct and natural extension of multiport, or “conventional,” laparoscopy, there are several unique aspects to LESS. Access is most commonly through the umbilicus as the “single site,” however, other locations can be utilized, such as a suprapubic or “mini-Pfannenstiel” approach, a transabdominal or retroperitoneal flank approach, or even a Gibson incision–retroperitoneal approach [5–7]. Access can be via a specialized port, or clustered conventional ports. A wide variety of purpose-built instrumentation and various options for imaging (e.g. rigid vs. flexible endoscopy) are available. For each LESS operation, although modifications in technique and maneuvers are often made, conventional laparoscopic techniques are largely followed. It is likely that advances in technology and, in particular, robotics will allow single-site access to be commonplace with expanding indications and outcomes data to support its use. This chapter will discuss these interesting facets of urologic LESS surgery of the upper tract.

## Trocar/port-site placement

### Umbilical and periumbilical

The majority of urologic upper tract LESS surgery is approached via an umbilical single-site access. Published reports of LESS have used all of the wide variety of access modalities available, both commercially manufactured and “homemade” designs created by surgeons using already available devices [1, 5, 8, 9] (Table 121.1). The umbilical trocar site is most often employed as it provides the opportunity to conceal incisions/scars. Multiport

**Table 121.1** Laparoendoscopic single-site surgery access modalities.

| Device | Features |
|---|---|
| Triport 15 (Advanced Surgical Concepts, Dublin, Ireland) | Two 5 mm ports, one 15 mm port reducible to 5 mm<br>Incision required: 1.2–2.5 cm<br>Disposable |
| TriPort + (Advanced Surgical Concepts) | Three 5 mm ports, one 10 mm port reducible to 5 mm<br>Incision required: 1.2–2.5 cm<br>Disposable |
| QuadPort + (Advanced Surgical Concepts) | Two 5 mm ports, two 10–12 mm ports reducible to 5 mm, one 15 mm port reducible to 5 mm<br>Incision required: 2.5–6.0 cm<br>Disposable |
| Endocone (Karl Storz, Tuttlingen, Germany) | One 10 mm port, one 10–15 mm port, six 3–5 mm ports<br>Incision required: 3.0–3.5 cm<br>Reusable |
| GelPoint Advanced (Applied Medical, Rancho Santa Margarita, CA, USA) | Three 10 mm ports. One 12 mm port. Accepts multiple conventional trocars or direct insertion of instruments<br>Incision required: 1.5–7.0 cm<br>Disposable |
| SILS Port (Covidien,Minneapolis, MN, USA) | Three foam insertion sites for passage of low-profile trocars<br>Incision required: 2.0 cm<br>Disposable |
| AnchorPort (ConMed, Utica, NY, USA) | Uses recirculating $CO_2$ to create seal, may pass multiple instruments through ports of varying calibers<br>Incision required: 1.5–2.5 cm<br>Disposable |

trocars, GelPort™/GelPoint Advanced™ devices (Applied Medical, Rancho Santa Margarita, CA, USA), or a clustered series of low-profile trocars can be employed within the umbilicus. Multiport trocar placement at the umbilicus requires a single incision, ranging from 2 to 5 cm to accommodate the chosen trocar (Figure 121.1). Use of separate low-profile trocars allows for more independent mobility and use of reusable devices, also using an incision ranging from 2 to 3 cm at the umbilicus (Figure 121.2).

Compared with conventional laparoscopy, during LESS surgery the laparoscope and working instruments are in much closer proximity to one another due to the nature of single-site access. This can necessitate the use of flexible scopes and/or instruments to avoid clashing and to allow for triangulation. The umbilical port site allows for adequate access to the upper tract urologic organs with the use of regular length instrumentation, in most cases.

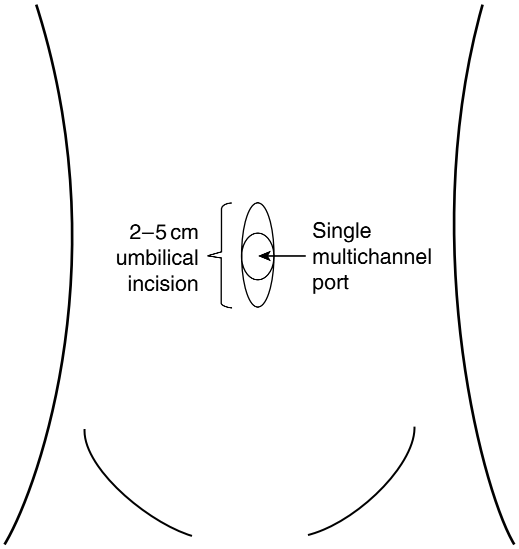

**Figure 121.1** Insertion of a multiport trocar at the umbilicus.

When treating obese patients, lateralization of the centrally located single incision toward the side of intended surgery may be necessary to offset length limitations of the operating instruments. The surgeon must consider whether this lateralized incision, no longer “hidden” within the umbilicus, still offers potential cosmetic advantages to the patient on a case-by-case basis. Alternatively, a retroperitoneoscopic LESS approach can be employed. Lateralization of the single site of access is akin to the lateralization of trocars employed during conventional laparoscopy in this patient population. Typically, this maintains the midpoint of the incision at the craniocaudal level of the umbilicus, but simply shifts it laterally toward the targeted kidney or adrenal gland, providing improved visualization with the laparoscope and simpler reach with the working instruments. Considerations when employing this modification in trocar placement include: the risk of developing incisional hernias, anatomic approach to traversing versus splitting muscle layers, as well as postoperative pain and cosmesis.

## Operative approach

A suprapubic approach has been reported for LESS simple, radical, and donor nephrectomy, as well as LESS nephroureterectomy. In selected patients, a cosmetic advantage may be obtained by concealing the single incision below the waistline. A small, or “mini-Pfannenstiel,” incision is employed that ranges between 5 and 8 cm in size. The size of the incision should allow for specimen extraction, but be as small as possible to optimize cosmesis. Access can be gained with a multiport device

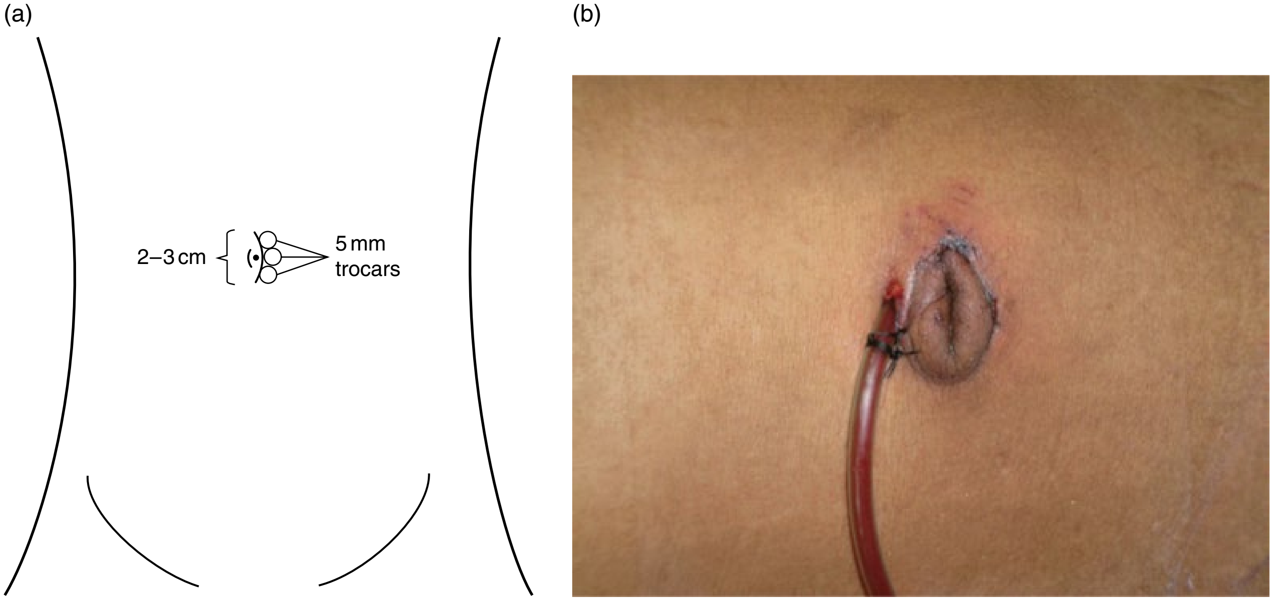

**Figure 121.2** (a) Insertion of three 5 mm low-profile trocars through a small umbilical incision. (b) Postoperative scars demonstrating positioning and proximity of trocars to the umbilicus.

(Figure 121.3) or using independently inserted, low-profile trocars [6, 10–12].

The suprapubic approach has more theoretical advantage in cases that require a sizable incision for specimen extraction, such as simple, radical, or donor nephrectomy or nephroureterectomy, in contrast to purely reconstructive surgery (e.g. LESS pyeloplasty) or surgery requiring extraction of small specimens (e.g. LESS cyst decortication or LESS partial nephrectomy). To allow for full access and ability to dissect circumferentially around the upper pole and posterolateral attachments of the kidney, it is useful to have bariatric and articulating laparoscopic instruments available.

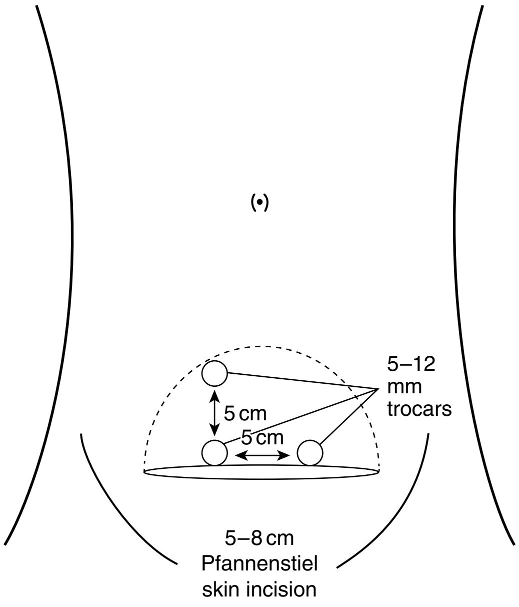

**Figure 121.3** Insertion of three 5-mm low-profile trocars through a Pfannenstiel incision.

Another approach gaining traction within recent years is single-incision triangulated umbilical surgery (SITUS). Retraction of the single umbilical incision allows the entry of several spaced working ports. Instrumentation is straight, standard laparosopic as spacing of the trocars allows triangulation of the target tissue.

## Use of accessory and needlescopic trocars

Although even complex reconstructive LESS procedures, such as pyeloplasty and partial nephrectomy, can be performed with no accessory points of entry [6], the use of accessory trocars or 1.9 mm needlescopic instruments has been reported extensively in the early experience of LESS. These added instruments act as an adjunct to the single-site approach and provide for instrument triangulation and added retraction, or can assist with intracorporeal suturing and knot tying. Accessory ports create a bridge between conventional laparoscopy and LESS, as surgeons learn LESS surgery. These ports play a critical role in challenging cases in which triangulation for adequate retraction and dissection is not adequately achieved with single-site access and available instrumentation.

With minimal to no morbidity, needlescopic instruments have been reported to enhance surgeon confidence and ensure patient safety during the diffusion of this new and challenging technique [4]. As experience with LESS increases and surgeons progress along the learning curve, the use of accessory trocars for assistance in triangulation and retraction will likely decrease. However, there will likely always remain an important role for accessory trocars or needlescopic instruments for more complex surgical cases. Moreover, additional access is always preferable to any compromise in safety or efficacy. Accessory trocars measuring from 5 to 12 mm in diameter have been reported. These are used by some urologists during LESS donor nephrectomy to allow for the expeditious and safe maneuvers necessary to limit the warm ischemia time of the renal allograft specimens. They also are adjuncts to LESS for complex reconstructive procedures or in patients with anatomic challenges requiring extensive adhesiolysis or body habitus limiting instrument flexibility. The site of accessory trocar placement can also be used as the location for drain placement at the culmination of the case.

## Extirpative surgery

### LESS nephrectomy

LESS nephrectomy can be performed for both “simple” nephrectomy and radical nephrectomy, for benign and malignant pathologies, respectively. Although done for differing indications, LESS nephrectomy has similar principles and maneuvers to conventional laparoscopic nephrectomy, with slight surgeon-specific modifications to overcome the novel challenges of the single-site approach of the operation [13].

The first laparoscopic extirpative surgery in urology was the laparoscopic nephrectomy reported in 1991, and this is now a relatively straightforward case often undertaken by new trainees prior to more complex renal surgeries [14]. Since the first LESS nephrectomy was reported in 2007 by Rane et al., the number has soared and remains the most common LESS urologic surgery performed [15]. A simple nephrectomy for non-oncologic indications allows for morcellation of the resection specimen. The most common location for trocar placement is at the umbilicus, and morcellation obviates the need to extend the umbilical trocar site incision, maximizing the cosmetic outcome [16]. However, extension of the incision is warranted in radical nephrectomies and nephroureterectomies to allow for passage of the entire kidney specimen intact for pathologic examination and appropriate staging without compromising the oncologic efficacy of the surgery.

Rane et al. described their initial experience with five LESS simple nephrectomies [16]. Their indications for simple nephrectomy included chronic reflux, recurrent infections, longstanding ureteropelvic junction obstruction, stone disease, and ureteral strictures, leading to poorly functioning symptomatic kidneys. In these cases of benign renal pathology, morcellation allows for an operative scar to be hidden within the anatomic folds of the umbilicus.

Since this report of LESS simple nephrectomies, other groups have reported LESS radical nephrectomy with adequate pathologic outcomes [5, 17, 18]. LESS radical nephrectomy has been reported through umbilical access as well as through a Pfannenstiel incision. In both circumstances, the incision is commonly 4–8 cm in length for purposes of specimen extraction, unless morcellation is employed. Despite requiring a larger extraction site, LESS radical nephrectomy still requires fewer incisions compared to conventional laparoscopy, and the incision is at least partially hidden within the umbilicus or within the skin creases of the suprapubic region, depending upon approach utilized.

In a series comparing LESS simple and radical nephrectomy to conventional laparoscopic nephrectomy, Raman et al. reported equivalent operative time, postoperative analgesic use, length of hospitalization, and rate of complications. Although the LESS cohort was found to have a lower recorded estimated blood loss, the change in hemoglobin concentration across the two patient groups was not statistically significant [17]. This was followed by a randomized controlled trial comparing LESS versus conventional multiport laparoscopic nephrectomy that demonstrated lower visual analog pain scores and decreased analgesic requirements for LESS surgery [19].

More recently, a similar study comparing patients with cT1–2 renal cell carcinoma showed superior postoperative Quality of Recovery-40 (QoR-40) questionnaire scores in the LESS group. Four out of five assessed dimensions were significantly improved in the LESS group; including emotional state, physical comfort, psychological support, and physical independence. Interestingly, pain was equivalent in the conventional laparoscopy and LESS groups [20]. Larger retrospective reviews have concluded LESS nephrectomy to have no significant differences in outcomes compared to the gold standard laparoscopic approach [21, 22]. A systematic review and meta-analysis of 25 retrospective studies showed that LESS nephrectomy is associated with longer operating time as well as a higher conversion to open rate compared with conventional laparoscopic nephrectomy. LESS was shown to offer advantages in terms of reduced postoperative pain, lower analgesic requirement, shorter length of stay, shorter recovery time, and better cosmetic satisfaction. Overall, there was no difference in terms of perioperative complication outcomes [23].

### LESS partial nephrectomy

Partial nephrectomy remains a challenging operation even when performed by multiport laparoscopy.

However, in selected patients, LESS partial nephrectomy has been demonstrated to be feasible and safe. LESS partial nephrectomy has been described without accessory trocars, technically replicating the conventional laparoscopic technique with careful hilar dissection for complete pedicle control, identification and excision of the tumor, and various hemostatic techniques coupled with the renorrhaphy (see Video 121.1) [5]. In efforts to minimize warm ischemia time and provide a hemostatic renorrhaphy, a 2 mm needlescopic accessory port is utilized by some experts for intracorporeal suturing [24]. As demonstrated by surgeons who have reported their experience with LESS partial nephrectomy, it is critical to convert to conventional laparoscopy in cases of limited exposure of the tumor resection site or when hemostasis is prohibitively challenging via a strict LESS approach.

Indications for conventional laparoscopic partial nephrectomy are expanding and now include resection of selected T1b tumors, central or hilar tumors, and multifocal tumors within the same kidney [25]. Currently, LESS surgery has been largely reserved for the strictest indications. In the renal LESS series reported to date, LESS partial nephrectomy was performed in a highly select patient population with ideal body habitus, limited prior abdominal surgery, and favorable tumor size and location.

A retrospective multi-institutional series analysis of a 190 cases was performed examining LESS partial nephrectomy and the resultant renal function as well as the short-term oncological outcomes. When hilar clamping was utilized, a significant increase in serum creatinine concentration and a significant decrease in estimated glomerular filtration rate (eGFR) were observed postoperatively and at six months. The degree of functional loss was correlated with the length of warm ischemia. The overall postoperative complication rate was 14.7%. Overall, survival rates were comparable to those following conventional laparoscopic partial nephrectomy. Furthermore, the authors found on univariate analysis that the robotic platform is a positive predictor for complication outcomes (predicts a complication is less likely to occur). On multivariate analysis, a low Padua Prediction Score was the only positive predictor for complications. It was concluded that the robotic platform can be a feasible and effective modality in terms of renal function and oncological control that may be likely to reduce postoperative complications [26].

When comparing robotic LESS to conventional robotic partial nephrectomy, one group found the robotic platform to have an increased warm ischemia time as well as total operative time but no significant differences in negative surgical margin rate, postoperative renal function, or complication rate. They also noted that the visual analog pain scale scores at discharge were significantly lower in the robotic cohort [27]. While these results are promising, these patient populations tend to be carefully selected, with the surgeries taking place at highly specialized facilities. One systematic review and meta-analysis comparing robotic LESS to conventional LESS partial nephrectomy highlights that these previous studies have shown promise in terms of complications, cosmesis, pain, as well as comparable postoperative renal function. Furthermore, robotic LESS partial nephrectomy has shown comparable oncological outcomes. However, they also show a trend for longer operative and warm ischemia times. They note the association between tumor size and positive outcomes, concluding that only highly selected patients should undergo robotic single-site approach. They see the benefits of the robotic approach, but emphasize the importance of technological innovations as well as an increase in high-quality data that appears to be lacking within the literature at this point [28].

## LESS nephroureterectomy

In addition to LESS radical and partial nephrectomy, LESS nephroureterectomy has been reported as an oncologic application of single-site surgery of the kidney. For the treatment of upper urinary tract transitional cell carcinoma, LESS nephroureterectomy has been reported by several centers [1, 5, 6]. As with conventional laparoscopy, both retroperitoneal and transperitoneal approaches have been described. Transperitoneal LESS nephroureterectomy has been reported via an umbilical as well as a Pfannenstiel single-site incision. Through a Pfannenstiel approach, after completion of laparoscopic mobilization and freeing of the kidney and ureter, a bladder cuff was performed in an open manner [6]. In reports of the retroperitoneal as well as umbilical approach to transperitoneal LESS nephroureterectomy, specimens were extracted through a separate Gibson incision measuring between 6 and 10 cm in length, through which a formal bladder cuff excision was also performed [5, 29]. This length of incision for management of the distal ureteral segment and intact specimen extraction was acknowledged in multiple published works as a contradiction to the goals of LESS to minimize total incisional length and associated pain and cosmetic concerns.

In addition, Lim et al. compared a traditional multiport robot-assisted approach to a robotic LESS platform. In this study, the robot-assisted LESS platform compared well in terms of oncological outcomes. However, the LESS approach had a significant increase of operative time, hospital stay, and blood loss. Furthermore, the LESS approach was more likely to need a blood transfusion [30].

## LESS donor nephrectomy

LESS donor nephrectomy has been pursued by advanced laparoscopists only after significant experience with LESS in other renal extirpative procedures. The technique described for LESS donor nephrectomy mimics the established methods of conventional laparoscopic living donor nephrectomy (LDN) first described in 1995 [31]. Important modifications unique to the LESS approach for LDN include the use of articulating or prebent instruments to overcome the challenges of single-port access and extra-long or bariatric instrumentation for adequate reach to the kidney, especially the upper pole and lateral aspects. Also, when selecting the mode of access for LESS donor nephrectomy, it is critical that the surgeon(s) preoperatively consider the approach to graft extraction, as minimization of ischemia time is imperative. With this in mind, the use of a multiport device that allows for extraction and rapid re-establishment of pneumoperitoneum may be preferable to clustered trocars.

Single-site donor series have been reported by several different transplant centers with advanced laparoscopists who were experienced at performing laparoscopic LDN [12, 32]. In this population of healthy volunteer donors, who are often related to the transplant recipients, safety is of the utmost concern. Therefore, the surgeon should maintain a low threshold to convert to multiport, hand-assisted, or open surgery in cases with a difficult anatomic approach or allograft procurement [1].

However, it is in this same population of young, healthy volunteers that the provision of a cosmetically superior result may be most valued by the patient. The initial publications on this less-invasive approach to renal allograft procurement describe efficacy and feasibility of LESS donor nephrectomy.

One study reporting a single-surgeon experience of six LESS cases matched to six conventional laparoscopic donor nephrectomies reported statistically comparable perioperative parameters, renal allograft characteristics, and postoperative pain [12]. Perioperative parameters evaluated and compared included operative time, warm ischemia time, estimated blood loss, and length of hospitalization. Postoperative pain was assessed by narcotic requirements and patient-reported scores on a visual analog pain scale. Notably, the median pain score reported at discharge in the cohort of LESS donor nephrectomy was zero on a 0–10 visual analog pain scale. None of the six LESS cases required conversion to conventional laparoscopy to complete the case safely, and all allograft specimens were adequate for successful transplantation and immediate function once implanted.

A matched-pair comparison of LESS donor nephrectomy to conventional donor nephrectomy revealed a quicker convalescence in the patient cohort undergoing LESS donor nephrectomy [33]. Parameters improved by the LESS approach included time on oral analgesics, time off work, and time to "100% recovery," as noted by patient questionnaires. In this study, warm ischemia time was statistically significantly higher in the LESS cohort; however, allograft function was noted to be immediate and comparable across the two groups.

Comparison analysis between Pfannenstiel LESS LDN compared to standard multiport LDN revealed significantly lower pain scores based on the visual analog pain scale, beginning on postoperative day one. All other perioperative parameters were equivalent between groups, including estimated blood loss, length of stay, and warm ischemia time [34].

A systematic review and meta-analysis of reports compared 461 LESS LDN cases to 1006 standard laparoscopic LDN. The review found laparoscopic LDN had a shorter operative time, without a significant difference in warm ischemia time. It also noted there was a greater likelihood of conversion to open for LESS LDN. The overall analgesic requirement was lower for LESS LDN. Moreover, there was no difference in the postoperative complication rate. The recipient renal function showed similar outcomes between groups. This review strengthens the argument that LESS LDN represents an emerging option for living kidney donation. This procedure offers comparable surgical and early functional outcomes to the conventional laparoscopic LDN, with a lower analgesic requirement. However, with a higher rate of conversion for LESS LDN, the technical challenge of LESS in LDN remains evident [35].

A recent Cochrane Review including three randomized control trials with a total of 179 patients was unable to determine if LESS LDN is an improvement upon laparoscopic LDN. Of all examined parameters, only pain scores at discharge differed significantly, favoring discharge. Interestingly, operative time and warm ischemia time were similar between the groups, suggesting that in experienced hands allograft function may not be affected with the LESS approach. However, the lack of consensus regarding the role of LESS in donor nephrectomy underscores the need for large, randomized control trials comparing LESS to conventional LDN [36].

## LESS adrenalectomy

The first conventional laparoscopic adrenalectomy was reported in 1992 [37]. Since then, laparoscopic adrenalectomy has been accepted as a feasible and safe minimally invasive option for the surgical treatment of various adrenal neoplasms [38]. For small to mid-size adrenal lesions, laparoscopic adrenalectomy has become standard practice not only for urologists but also general surgeons at some centers. Debate exists regarding the efficacy of laparoscopy for the treatment of known or suspected adrenal cortical carcinoma, particularly for larger masses.

One of the earliest reports of LESS adrenalectomy was of retroperitoneoscopic adrenalectomy via a 4.5 cm trocar without the use of insufflation [39]. In this report, 53 patients with adrenal tumors were treated successfully via this approach and one patient (1.9%) required conversion to open surgery secondary to excessive blood loss from an adrenal vein injury. Other approaches have been utilized in order to achieve consistent perioperative outcomes while maximizing cosmetic results. In a comparison of the transumbilical, transperitoneal subcostal, and retroperitoneal subcostal approaches, the transumbilical approach was rated as the most favorable cosmetically [40].

In a contemporary series, nine patients undergoing LESS adrenalectomy for benign adenoma were compared to 17 patients undergoing conventional laparoscopic adrenalectomy [41]. Patients were matched with regard to age, sex, surgical indications, and tumor size. Operative time, blood loss, and hospital stay were found to be equivalent. The LESS group demonstrated a shorter period of postoperative intravenous patient-controlled analgesia use.

A more recent meta-analysis compared LESS to conventional laparoscopic adrenalectomy including 704 total cases. It was determined that LESS patients benefited from shorter length of stay as well as improved pain scores. There were no significant differences in terms of the operation or oncological outcomes, concluding that LESS adrenalectomy could be the more preferred technique. This conclusion is strengthened by recent data showing that LESS has the fastest increase in yearly utilization with much of these increases being in Asia. In the United States, the trend is moving toward robot-assisted adrenalectomy [42].

## Reconstructive surgery

### LESS pyeloplasty

Pyeloplasty is the most common reconstructive upper tract urologic surgery performed. With the advent of laparoscopic pyeloplasty in 1993, there was a significant movement toward a minimally invasive approach rather than the large, muscle-traversing flank approach for open pyeloplasty, which was the former standard [43]. Since the development and diffusion of laparoscopic pyeloplasty by urologists, both dismembered and Y-V laparoscopic pyeloplasties have been performed in large series with reliable postoperative outcomes [44, 45].

As with LDN, patients undergoing pyeloplasty are often young and healthy, without malignant pathology, and cosmesis may be of greater concern to them. A cohort of LESS pyeloplasty patients demonstrated a younger mean and median age when compared to other LESS upper tract operations in a single institution experience of upper tract urologic LESS [5]. Heightened efforts to minimize the overall incision burden and subsequent appearance of cutaneous scars in this population seem appropriate. Ongoing research is aimed at further defining the quality of life and cosmetic advantages that LESS urologic surgery may provide.

LESS pyeloplasty can be performed with or without the use of accessory trocars [5]. All techniques and associated procedures can be performed via LESS, including dismembered pyeloplasty, Y-V pyeloplasty, pyeloscopy, and stone extraction. We advocate flexible cystoscopy and placement of a 7 Fr, 28 cm double-pigtail ureteral catheter prior to commencing with the LESS portion of the procedure. Other surgeons advocate a smaller 6 Fr stent to facilitate positioning of the scissor blade between the stent and ureteral wall, and thereby facilitating spatulation. Still other surgeons prefer an antegrade approach to stent placement during laparoscopy. Although we consider rigid straight laparoscopic instruments to be sufficient for nearly all LESS surgery, spatulation of the ureter may be facilitated by the use of articulating scissors in some cases.

Conventional laparoscopic salvage pyeloplasty has been reported with promising results [46, 47]. However, to date, LESS pyeloplasty is reserved for idealized patients undergoing primary pyeloplasty for congenital ureteropelvic junction obstruction. LESS pyeloplasty can be performed in the setting of a crossing vessel, as dismembered, transposed pyeloplasty can be performed effectively.

Short-term postoperative outcomes have been reported for LESS pyeloplasty and compared to historical controls undergoing conventional laparoscopic pyeloplasty. In a study reported by Raman et al., LESS pyeloplasty resulted in comparable perioperative and functional outcomes [48]. All perioperative parameters were equivalent, except for operative time and estimated blood loss, which were found to be significantly lower in the LESS cohort of patients.

A multi-institutional study by Schwartz et al. showed LESS pyeloplasty to be a safe option with success rates equivalent to conventional laparoscopic pyeloplasty [49]. In this series, the only clear benefit noted in the period of short follow-up was that of minimized incision size and postoperative scar formation, although postoperative pain and analgesic requirements were not assessed.

A more recent, longer term, multi-institutional study of 140 patients undergoing unilateral LESS pyeloplasty revealed a durable cure rate at mean follow-up of 14 months with a perioperative complication rate of 18.6%. Of these patients, 93.4% reported symptomatic resolution and 94.4% exhibited radiographic resolution of obstruction. Postoperative nuclear scans revealed improvement in 86.5% of patients. These findings were mirrored in a systematic review by Brandao et al. who concluded LESS pyeloplasty is comparable to conventional laparoscopic technique with regard to surgical and functional outcomes. Although LESS can be more technically challenging, it provides advantages in terms of decreased analgesic needs [50, 51].

LESS utilizing robotic assistance has also been explored. A pilot study recently reported the feasibility of a robot-assisted LESS pyeloplasty for ureteropelvic junction obstruction at two surgical centers. Of the 31 cases, two needed to be converted to either a standard laparoscopic or robotic procedure. No intraoperative complications were reported. The majority of postoperative complications were Clavien classification I or II. A success rate of 93%, defined as symptomatic and functional imaging improvement, at a median follow-up of 13 months was seen. Given this information, more prospective comparative studies versus standard robotic techniques are needed [52]. One systematic review highlights this sentiment, stating there is a need for more prospective studies [53]. Of the literature reviewed, they note that surgeons prefer the single-site approach because it makes dissection and suturing easier compared to the traditional robotic platform. However, a common complaint among surgeons was the issue with instruments clashing. They conclude the robotic LESS approach can become a viable option, but advances in technology appear to be the main roadblock in reaching the ultimate goal of providing a safe and easy surgical modality that can be widely disseminated among the general population.

## Ablative surgery

### LESS cryoablation

Cryoablation has been demonstrated as an oncologically effective means of providing focal ablation therapy for the treatment of small renal masses, maintaining a nephron-sparing result [54]. Both laparoscopic and percutaneous image-guided approaches have been well described for renal cryoablation. Benefits of the laparoscopic approach to renal cryoablation include direct visualization of probe placement, monitoring the ice-ball formation visually or with intraoperative ultrasonography, and the means to mobilize bowel or other adjacent structures safely away from the area of focal ablation [55]. Transperitoneal as well as retroperitoneoscopic entry have been reported, differentially used based primarily on the anatomic location of the renal mass being ablated.

The technique for LESS cryoablation, using both transperitoneal and retroperitoneal approaches, was first reported in a human series in 2008 [56]. Since this initial report, LESS cryoablation has been reported by a number of different institutions as part of larger urologic LESS series in the literature [1]. To date, the literature has demonstrated LESS cryoablation to be a successful approach with acceptable perioperative parameters when compared to conventional laparoscopy. Although only a small number of cases were observed in one study, there was no conversion to conventional laparoscopy showing overall promise for this modality [56]. However, LESS cryoablation is at a very early stage of the learning curve of LESS surgery with an obvious need for more studies.

Renal cryoablation provides an ideal opportunity for LESS because there is no specimen necessitating an extraction site. Also, intracorporeal manipulation is limited to mobilization of adjacent organs and intraoperative imaging with ultrasonography, while other LESS renal surgeries require advanced intracorporeal suturing techniques or vascular clamping and manipulation that are more easily achieved with the triangulation provided by conventional multiport laparoscopy.

### LESS cyst ablation/decortication

Laparoscopic and LESS management of renal cysts provides minimally invasive access to either aspirate and sclerose the cyst cavity, ablate the lining, or decorticate symptomatic renal cysts. Decortication by excision of the cyst wall with luminal fulgration using either an argon beam coagulator or electrocautery provides the most durable long-term outcome based upon rates of recurrence [57, 58].

Experience with LESS cyst decortication has often been presented in larger LESS series encompassing multiple operative procedures [1, 29, 59]. LESS cyst decortication has been reported through periumbilical access, providing a transperitoneal approach as well as a retroperitoneal approach through a multichannel access port placed in the flank. Operative techniques vary based upon the location of the renal cyst being targeted as well as the complexity of the dissection required to expose the cyst for decortication. A combination of standard laparoscopic and articulating laparoscopic instruments has been reported to aid in these LESS cases. Also, one report cited use of an operative laparoscope to further minimize the access ports required, allowing for successful retroperitoneal LESS cyst decortication [7]. An additional study described the use of a homemade glove port to facilitate LESS in symptomatic cyst decortication in 62 patients. No major operative complications were reported in this series [60].

Patients with large renal cysts, reported as large as 15 cm, have been safely and successfully managed with LESS surgery, with minimal intraoperative blood loss and discharge commonly on the first or second postoperative day [1, 7, 59]. The length of hospitalization is likely a result of the early learning curve of LESS surgery. As with laparoscopic renal cryoablation, conventional laparoscopic cyst decortication has been reported as an ambulatory operation in experienced centers [61]. Unfortunately, comparative studies with conventional laparoscopy are lacking. Future research should focus on comparative perioperative outcomes with conventional laparoscopy since conventional laparoscopy already provides such remarkable outcomes. However, if equivalent outcomes can be achieved, the improved cosmesis of LESS surgery alone makes it an attractive option.

## Robotic single-port surgery

Robotic surgery has become a mainstay in the treatment of a number of urologic conditions. Though its experience with LESS procedures is not as well described, there has been significant growth in this area within the last several years. The first urologic robotic LESS procedure was described in 2007 by Raman et al., who performed robotic LESS nephrectomy in porcine models [62]. Typically, a single-site incision is made at the umbilicus with multiple fascial incisions made for multiple port sites. A single port incision can also be made with a single fascial incision for the multichannel port.

To date, the robotic single-site emergence has led to more surgical centers attempting robotic LESS, resulting in comparison studies between the robotic LESS approach and the traditional robotic technique with initial positive results. However, this was not without immediate drawbacks and obstacles. Some of the early hurdles include: bulky components that would result in external clashing, limited access for the bedside assistant, difficulty maintaining triangulation toward the target anatomy, and inability to use the fourth arm. A number of studies have been performed reporting novel technologies or strategies seeking to improve efficacy and troubleshoot some of these challenges. Advances that have enhanced overall functionality and usability of the single-site robotic platform include: use of a multiport GelPort™ at a single incisional site previously described in this chapter, changes in the robotic platform to accommodate the single-site technique, and positional changes such as the “chopstick” technique, where the robotic arms cross each other at their point of entry [63].

The da Vinci SP1098 instrument arm is a new modification allowing the triangulation of target tissue during robotic single-port surgeries. The instrumentation is unique in that it is double-jointed, with elbow and wrist articulating joints, improving maneuverability and expanding the workspace. A recent cadaver trial focusing on retroperitoneal LESS radical and partial nephrectomy without comparison control group revealed no complications or conversions. Although large-scale data are lacking, this technology may be a solution to limitations caused by instruments entering from a single point and may expand the role of robotics in LESS surgeries. As practitioners and product developers continue to troubleshoot, the robotic single-site modality will continue to grow within urologic surgery [53].

## Future of LESS for upper tract urologic surgery

The dissemination of advances in surgical technique is dependent upon the realized value of these new developments. Furthermore, the technique must prove reproducible beyond selected centers of excellence. LESS has proven its versatility based upon the wide range of urologic operations for which it has been successfully employed as an extension of conventional laparoscopy. As experience with LESS expands in some centers, more novice surgeons, including residents and fellows enrolled in urology training programs, are being exposed to these new techniques within an apprenticeship model. Also, as skill centers are using inanimate box trainers and electronic simulators as an adjunct aide in laparoscopic training outside the operating room, new LESS training modules should be developed to augment the breadth of these simulator platforms.

A recent anonymous questionnaire was electronically mailed to members of the Endourological Society and the American Urological Association with regard to LESS. Although 44.7% of respondents had stated they had performed LESS, only 25% of those surgeons had done more than 10 cases. Only half of the respondents believe that LESS should be taught in residency, which may be a point of contention if LESS is considered strongly by accrediting bodies. The results also show that a majority of respondents (68.7%), no matter their experience in LESS, do believe in the cosmetic results. However, respondents also commonly felt that LESS does not produce a quicker recovery or improved postoperative pain, which contradicts much of the research presented throughout this chapter, increasing the need for more prospective comparative studies [64].

As LESS has gained traction to become more of a mainstream technique one would expect use to rise among minimally invasive urologists. Unfortunately, there is a relative lack of data regarding trends of utilization. A recent analysis of over 700 adrenalectomies performed worldwide at 14 institutions revealed 36% performed using LESS techniques versus 46% with conventional laparoscopy. While this speaks to the growth of LESS worldwide, larger studies on a variety of urologic procedures are necessary to adequate gauge patterns of use [42].

A number of research efforts are currently underway to develop improved instrumentation and access platforms to facilitate LESS. Motorized articulating instruments and robotic platforms will become available that will help overcome the inherent challenges of single-site surgery. Published reports have described the use of the da Vinci Surgical System as an adjunct to LESS urologic techniques [8, 65]. Currently, under investigation are magnetic anchors and intracorporeal robotic mechanisms with the goal of minimizing the number and length of incisions, as well as providing better triangulation in LESS cases [66]. These innovations are not only troubleshooting traditional LESS surgery, but also robotic LESS surgery, as described earlier. In the future, it is imperative that prospective studies focus on patient quality of life and postoperative satisfaction, keeping outcomes such as cosmesis in mind. These studies will continue to push the envelope in order to create a platform that can be distributed on a global basis without concerns for patient care and clinical outcomes.

## Introduction

The use of robotic platforms in urologic surgery has become widely prevalent secondary to the benefits it provides over conventional laparoscopy, including enhanced three-dimensional optics, improved instrument control and dexterity, and superior ergonomics. These technological advancements have resulted in the adoption of robotics in laparoendoscopic single-site (LESS) surgery to surmount difficulties associated with intra-abdominal triangulation and intracorporeal suturing. The first robotic laparoendoscopic single-site surgery (RLESS) series was published in 2008 [1], and since that time, various studies have demonstrated its application in lower tract urologic procedures [2–8]. Although the benefits afforded by the application of the robotic platform are tremendous, major limitations inherent to single-site surgery still exist, including bulky external mechanics, instrument clashing, and limited space for the bedside assistant surgeon. Although many technical improvements have been described to tackle these challenges, pelvic RLESS is still evolving and has not been widely embraced [9, 10].

Several aspects of conventional robotics cross over to RLESS, including operating suite layout, instrumentation, and surgical draping. The main difference between the two approaches is port-site access and docking. RLESS typically utilizes ports that are more obliquely placed to one another in order to limit external clashing. The specific steps of each procedure are similar, though some creativity must be used when employing RLESS to address the aforementioned challenges. This chapter discusses the tools, techniques, published outcomes, and up-and-coming technology associated with specific urologic RLESS procedures of the lower urinary tract. In addition, a video has been included to demonstrate our technique for performing RLESS perineal radical prostatectomy utilizing a novel single-port robotic platform (see Video 122.1 ).

## Robotic docking for RLESS technique

In terms of docking, a few noteworthy differences exist between traditional multisite robotic surgery and RLESS. The authors typically prefer the da Vinci Si or Xi models versus the S model due to the improved optics and ergonomics. The Xi model offers a more compact, sleeker external profile of the patient cart, which may allow for decreased external clashing. In addition, only three robotic arms are using during pelvic RLESS surgery as there is limited space to accommodate the additional robotic instrument arm.

Other techniques which may limit external clashing include the "chopstick" technique popularized by Joseph et al., in which the robotic instruments are crossed at the fascial level in order to create more working space between the robotic arms outside of the surgical field [11]. This technique was previously utilized in the traditional LESS approach but proved to be very challenging due to the "reverse-handedness" associated with crossing of the instruments. A major benefit of applying the robotic platform to LESS is the ability to control each instrument electronically, permitting the interchange of instruments and master controllers, effectively removing the limitation of "reverse-handedness." The main limitation of the chopstick technique is the trade-off of external clashing for internal clashing. Crossing of the instruments at the fascial level results in the deflection of the instruments where their shafts

cross. The surgeon must always be aware of the position of each instrument to avoid any counter-springing associated with exaggerated movements.

## Pelvic surgery

### Radical retropubic prostatectomy

For radical retropubic prostatectomy we favor obtaining single-site access using a multichannel SILS port (Medtronic, Minneapolis, MN, USA). For this technique, all of the robotic ports occupy the same skin incision but enter the intra-abdominal space through separate fascial incisions. The robotic camera port, bedside assistant port, and insufflation tubing are placed through the SILS port at the lower aspect of the umbilicus. Arrangement of the operative suite, patient positioning and docking are the same as conventional robotic radical prostatectomy, with the patient positioned in dorsal lithotomy and steep Trendelenburg with the robotic cart docked between the patient's legs. The multichannel port is inserted at the inferior aspect of the umbilicus through the linea alba of the rectus fascia. The 8 mm lateral robotic ports are placed at the lateral-most inferior edge of the skin incision and are skived through the subcutaneous fat as far laterally as possible to approximate the positioning used for the traditional approach. The fourth instrument arm is not used for the RLESS technique. Using this port arrangement, the "chopsticks" method is not needed.

The major steps of performing RLESS retropubic radical prostatectomy are the same as those used for the conventional robotic approach. Initially the bladder is mobilized to develop the space of Retzius using an 8 mm curved monopolar scissor in the right arm and an 8 mm ProGrasp forceps or a 5 mm Schertel grasper in the left arm. Use of a 30° up scope initially may be beneficial for controlling and ligating the urachus. The bladder is dropped from the anterior abdominal wall, and the anterior surface of the prostate is defatted to expose the endopelvic fascia and dorsal venous complex (DVC). The endopelvic fascia is opened, and the DVC is identified and controlled with 2-0 braided polyglactin suture using an 8 mm robotic needle driver in the right arm. The junction between the bladder and prostate is then identified, and the bladder neck is opened in order to expose the urethral catheter. Identification and dissection of the bladder neck is facilitated by having the catheter balloon deflated and the catheter advanced all the way into the bladder. Once the bladder neck is open, the catheter is pulled up into the field. A "marionette" suture is used to secure the catheter to the anterior abdominal wall, as was explained in our initial RLESS series [1]. This allows for anterior retraction of the prostate during posterior dissection. Once the prostate is completely freed from the bladder neck, the anterior Denonvilliers' fascial layer is identified and opened to reveal bilateral vas deferens and seminal vesicles. When nerve sparing is not performed, energy may be used during this dissection. If nerve sparing is planned, energy should be avoided. The posterior dissection is performed from the base of the prostate to the apex, carefully releasing the rectum. Once the posterior plane is complete, bilateral nerve sparing is performed (when appropriate), along with bilateral control of the prostatic vascular pedicles. Once this is done, attention is turned to the prostatic apex. We typically perform a meticulous apical dissection to ensure the longest urethral length possible while avoiding positive margins. The urethra is sharply transected. Once the prostate is removed from the pelvis, bilateral pelvic lymph node dissection is performed. Once the lymph nodes are removed, the vescicourethral anastomosis is performed using two 8 mm robotic needle drivers in the left and right arms. We typically perform our anastomosis in a running fashion with two 2-0 poliglecaprone 25 sutures on RB-1 needles. At the end of the procedure, the anastomosis is tested by instilling 200 ml of sterile saline into the bladder, and a 10 mm Jackson–Pratt drain is routinely left. A separate facial stab incision is made for placement of the drain, but the drain is externalized via the same skin incision used for the multichannel port, thereby limiting the number of skin incisions.

### Robotic single-port transvesicle enucleation of the prostate

In 2010, our institution described robot-assisted single-port transvesicle enucleation of the prostate (R-STEP) [6]. This technique involves the use of the GelPort (Applied Medical, Rancho Santa Margarita, CA, USA) through a suprapubic incision that allows port placement directly into the bladder for transvesicle enucleation. Patients are placed in low lithotomy position, and cystoscopy is performed prior to port placement in order to define the apical limits of the prostate using a Collins knife. The bladder is filled with irrigation, and the skin incision is marked from the level of the dome of the bladder downward toward the pubis. Identification of the cranial-most extent of the incision is facilitated with the use of a spinal needle placed under cystoscopic vision directly into the bladder. Once this limit is defined, a 3 cm skin incision is made through the fascia, and the perivesicle fat is dissected away to expose the underlying detrusor. Two stay sutures are placed along both sides of the detrusor opening. The bladder is opened transversely between the stay sutures. A 16 Fr catheter is placed into the bladder, and the balloon is inflated with 5 ml of sterile water. The GelPort is then placed through the wound in order to allow access into the bladder. We use a 12 mm port at the 6 o'clock position for the robotic camera and insufflation, two 5 mm ports on the right and an 8 mm robotic instrument port on the left. The GelPort gel pad comes with a premade hole in the center to assist with trocar placement, which is closed prior to placement of the gel pad over the wound retractor since it is not used in this technique. Once all the ports are placed, the bladder is insufflated to 20 mmHg. An upward-facing 30° scope is used during this procedure to improve visualization and to limit instrument clashing. The 5 mm harmonic scalpel is used in the right arm and a 5 mm deflecting Schertel grasper is placed in the left. A circular incision is made around the prostatic adenoma between the prostate and bladder neck. Care is taken to identify and avoid the bilateral ureteral orifices during this initial dissection. The avascular plane is developed between the prostatic adenoma and prostate capsule, and enucleation is carried out from the prostatic base to the apex. The incision made at the apical prostate at the beginning of the case assists with identification of the apex during this dissection. Once this is complete and bleeding is controlled, a 24 Fr three-way hematuria catheter is placed into the bladder with 30 ml of sterile water in the balloon. The specimen is removed from the bladder via the GelPort site, and the bladder is closed in a running fashion with 2-0 absorbable suture. The rest of the wound is closed in the standard fashion, using 0-0 PDS for the fascial closure.

## Perineal robot-assisted laparoscopic prostatectomy

Our institution has recently begun performing robot-assisted radical prostatectomy via a perineal approach in select patients [7]. Perineal robot-assisted laparoscopic prostatectomy (P-RALP) is beneficial in cases with prior history of extensive abdominal surgery, radiation, or gastrointestinal or urinary diversions. In addition, removal of the prostate from a perineal approach offers similar benefits to a posterior, space-of-Retzius-sparing technique by preserving the endopelvic fascia and pelvic floor diaphragm [12–15]. The steps of this procedure are outlined in Video 122.1 that accompanies this chapter.

To begin, a 3–4 cm semilunar perineal incision is made between the ischial tuberosities, similar to open perineal radical prostatectomy, and the central tendon is divided. A GelPOINT multichannel port (Applied Medical) is placed after the space is created by transection of the rectourethralis muscle (Figure 122.1). We utilize a 12 mm camera port, two 8 mm robotic ports, and a second inferior 12 mm port for assistant access (Figure 122.2).

Once the robot is docked, the posterior prostatic space is developed to expose the levator ani muscles on either side. The levator fibers are split along the lateral aspects of the prostate, and Denonvillier's fascia is opened. This is done in a fashion to preserve the neurovascular bundles bilaterally. The posterior plane of the prostate is followed to find the insertion of the seminal vesicles and vas deferens bilaterally. The bilateral vascular pedicles to the prostate are identified and ligated (Figure 122.3). The prostatic apex is dissected, and the urethra is cut sharply (Figure 122.4). The catheter is clipped prior to transection in order to maintain fluid in the catheter balloon so that the catheter can be used for traction on the prostate. The junction between the bladder neck and prostate is identified, and the bladder neck is opened (Figure 122.5). The catheter is removed, and the remaining prostatic attachments are completely released. The vesicourethral anastomosis is performed in a running fashion over a new catheter beginning anteriorly (Figure 122.6). The anastomosis is tested with 200 ml of sterile saline. At this point, the robot may be undocked and the prostate removed via the perineal incision.

Currently, we have published on our P-RALP results in two patients with promising outcomes [8], and since our

initial publication, our experience has grown to include five additional patients with good oncologic control and functional outcomes. This approach is feasible and thus far has not required conversion to standard open, robotic or laparoscopic techniques. We also have demonstrated the feasibility of this approach in a cadaveric model using a novel single-port robotic platform. This platform will be discussed later in this chapter. The P-RALP technique is still in its infancy, and our future experience with this approach is forthcoming.

### Radical cystectomy

The initial LESS radical cystectomy series, which included three patients with muscle-invasive bladder cancer, was published in 2010 by Kaouk et al. [16]. Mean estimated blood loss was 217 ml, mean operative time was 315 minutes, and mean length of stay was 6 days. All diversions were performed via the umbilical port site with minimal extension of the incision. Median node yield was 16. All surgical margins were negative, and there were no recurrences at 2-year follow-up. In 2012, White et al. published a series of RLESS cases, which included three radical cystectomies with extended pelvic lymph node dissections [4]. Rectal injury occurred in one case. This was recognized intraoperatively and repaired during the surgery with no sequelae. Data regarding outcomes after single-site radical cystectomy are limited in the literature. The aggressive nature and possible lethality associated with muscle-invasive bladder cancer has greatly limited RLESS as a widespread treatment option, as oncologic outcomes of conventional open and robotic approaches greatly outweigh the cosmetic benefits associated with single-site surgery. Therefore, more studies are required before RLESS techniques are deemed viable options for muscle-invasive bladder cancer.

## New single-port technology

Combining LESS with the robotic platform has greatly enhanced our surgical capability by offering increased articulation and stability for precise suturing and dissection. While the da Vinci robotic system has substantially improved our ability to perform single-site surgery, it was not originally designed for this purpose. For this reason, an innovative purpose-built, RLESS system has been developed. In contrast to the original robotic design for single-site surgery that required the use of multiple separate ports, the da Vinci single-port (SP) system only uses a single port to introduce the instruments and camera. This system uses the same base of the patient sidecart as the da Vinci Xi robotic system and is adapted onto a single arm.

Kaouk et al. described the first clinical application of the new single-port robotic system in 19 patients, 11 of whom underwent single-site robotic prostatectomy [17]. There were no conversions to open, contemporary robotic, or laparoscopic techniques, and high-grade complications only occurred in two patients. Functional outcomes over a 3-year follow-up were comparable to standard techniques. This new single-port robotic technology represents a step forward in minimally invasive surgery. It is unique as it allows for intracorporeal triangulation, while eliminating instrument clashing seen with other methods of single-site surgery. The SP999 platform was used by our group in a cadaveric model to perform three perineal radical prostatectomies, including two perineal pelvic lymph node dissections. The outcomes from this feasibility study are not yet published. Mean operating time was 210 minutes, and no conversions to alternative techniques were required. No intraoperative complications were seen.

More recently, a next-generation single-port robotic system (SP1098) has been evaluated for performing extraperitoneal urologic procedures in a cadaveric model [18]. Three perineal radical prostatectomies and two perineal pelvic lymph node dissections were successfully performed using this novel SP platform. Its application was found to be to be feasible in extraperitoneal abdominal and pelvic surgery. Most recently, the SP1098 was used to perform perineal radical cystectomy and extended pelvic lymphadenectomy to the level of the inferior mesenteric artery in two male cadavers without complications or conversions, though this series has not yet been published. Further clinical trials will be needed in order to better define the role of the SP1098 role in minimally invasive single-site surgery.

## Conclusions

The adaptation of the robotic platform to LESS has greatly improved the ability to perform single-incision pelvic surgery, mainly by instituting improved optics and articulating wrist technology as offered by robotic instrumentation. Although this approach has improved over time, there has not been widespread adoption of RLESS secondary to innate challenges that still exist, including instrument clashing and limited bedside access for the surgical assistant. A novel device specifically designed for single-port robotic surgery will be introduced in the near future and will improve our ability to perform these procedures. The field of minimally invasive surgery continues to expand its horizons with each new technique and device that comes to market. There is no doubt that these new approaches will continue to push the limits of minimally invasive urology, especially as it relates to lower urinary tract surgery.

## Introduction

Over the last 35 years, the evaluation of renal masses has been revolutionized by technical advances in ultrasound, multidetector computed tomography (MDCT), magnetic resonance imaging (MRI), positron emission tomography–computed tomography (PET-CT), and positron emission tomography–magnetic resonance imaging (PET-MRI) [1–4].

It is estimated that 50% of people over the age of 50 years have at least one renal mass that can be detected on cross-sectional imaging [5–7]. Most of these lesions are benign simple cysts that can be diagnosed with confidence and require no further evaluation or treatment [8]. However, most renal neoplasms are now found incidentally while evaluating the patient for other suspected pathology [1]. The role of the radiologist is not only to detect these renal lesions, but also to distinguish between benign and malignant masses, and to help direct the management of these lesions.

Over the past 20 years, the treatment of renal masses has become increasingly individualized, with therapeutic options ranging from radical nephrectomy, laparoscopic nephron-sparing surgery, to laparoscopic or imaging-guided cryotherapy and radiofrequency ablation [9–14]. Novel molecular targeted chemotherapy has also been instrumental in prolonging patient survival in patients with advanced renal neoplasms.

This chapter reviews the role of CT, MRI, ultrasound, PET-CT, and PET-MRI in guiding the increasingly sophisticated process of characterizing and managing renal masses. Guidelines concerning the most efficacious use of the various imaging modalities with a view toward optimizing patient management are presented.

## Imaging techniques

### Multidetector CT

Recent improvements in MDCT technology allow thinner collimation and faster scanning that provides multiphasic, high-resolution images of the kidneys. These hardware developments, coupled with advances in three-dimensional imaging software and the availability of cheaper data-storage capacity, have provided new opportunities for imaging renal and urinary tract pathology. Isotropic imaging of the kidneys, ureters, and bladder is now possible, providing two-dimensional multiplanar reformations (MPR), CT urography (CTU), and three-dimensional imaging formats, with minimal artifacts, all derived from a single data acquisition [15, 16]. The kidneys can be scanned in less than 5 seconds, allowing for acquisition of thin-section images during the corticomedullary, nephrographic, and excretory phases. This multiphasic evaluation permits high-resolution imaging of not only the renal parenchyma but also the renal vasculature and collecting system.

Evaluation of a renal mass by CT requires a dedicated multiphasic CT protocol which may include: a precontrast scan; arterial phase (15–25 seconds delay) scan; corticomedullary phase (35–80 seconds delay) scan; nephrographic phase (85–180 seconds delay) scan; and excretory phase (>3 minutes delay) scan. The radiation dose in the CT urography protocol is approximately 10–12 mSv. In order to reduce the patient radiation dose, the precontrast, nephrographic phase, and excretory phase scans are the ones most commonly obtained [15–17].

Noncontrast scans of the kidneys are performed initially to evaluate for the presence of fat or calcification in the

mass and to detect nephrolithiasis. This scan also provides a baseline from which to quantitate lesion enhancement on postcontrast scans. The scans performed during the arterial or corticomedullary phase, while limited for mass visualization, nicely display the renal vasculature, which is critical for surgical planning, particularly when partial nephrectomy is being considered. Arterial phase scans best show small hypervascular neoplasms and the renal arteries. The nephrographic phase optimizes mass visualization. The delayed phase scans are helpful in assessing the relationship of the renal mass to the renal collecting system and also visualizing the remainder of the urinary tract. The data from these various series can then be reconstructed at thinner intervals and transferred to a workstation where multiplanar reformatted images, maximum intensity projection (MIP) images, and 3D volume rendered images can all be created [15–17].

Contrast enhancement and subsequent de-enhancement are characteristic features of renal malignancies. A renal lesion is considered to be enhanced when its density increases more than 20 Hounsfield units (HU). If the density of the lesions increases between 10 and 20 HU, it is considered indeterminate for enhancement and requires further testing. While these criteria seem straightforward, the accuracy of determining enhancement varies based on the type of CT scanner used as well as technical factors including the kilovoltage and amperage of the X-ray beam, pixel size, image noise, slice thickness, beam-hardening artifacts, and artifacts related to large body habitus. The size of the lesion is also important because volume averaging commonly occurring in lesions smaller than 10 mm in size.

Pseudoenhancement occurs when a cyst, usually <2 cm, appears to artifactually enhance because it is surrounded by strongly enhancing parenchyma. This typically occurs during peak renal enhancement and should be suspected when a lesion is homogeneous and measures less than 10 HU on an unenhanced CT scan [18–21].

Dual-energy CT (DECT) is a recent development that involves the simultaneous acquisition of CT data at two different peak tube voltages and has the potential to reduce radiation dose. By exploiting the differences in energy-related attenuation of tissues within the body, DECT potentially can characterize tissue composition to a greater extent than that possible with single-energy techniques. When this technique is applied to remove the iodine contribution for a postcontrast image, a virtual noncontrast image can be produced. This technique exploits the fact that soft tissue and iodine demonstrate unique attenuation differences at different tube voltages, allowing for material decomposition. This technique also makes it possible to measure iodine concentration (instead of attenuation values) within the lesion. Enhancing renal masses demonstrate the presence of iodine, whereas benign, nonenhancing lesions have an absence of intralesional iodine.

## Magnetic resonance imaging

Significant advances in MR imaging hardware and software with routine use of phased-array coils and parallel imaging permit fast and high spatial resolution imaging of the kidneys. Short breath hold scans can produce superb multiphase renal images without significant peristaltic or respiratory motion artifacts [22–25]. The following imaging sequences should be obtained when evaluating a renal mass with MR: coronal T2-weighted single-shot turbo spin-echo sequence to serve as a localizing scan; axial T2-weighted gradient and spin-echo sequence with fat suppression to search for renal mass invasion of the adjacent fat; a dual-echo axial T1-weighted gradient-echo sequence with in-phase and opposed-phase images to search for fat within the tumor; and an axial T1-weighted fat-suppressed gradient-echo sequence for dynamic imaging using 20 ml of intravenous gadolinium with precontrast and postcontrast images obtained during the arterial, corticomedullary, and nephrographic phases to assess tumor vascularity. The physiologic principles behind the various dynamic postcontrast phases described in the MDCT section also hold true for dynamic MR imaging [26].

MR-derived functional imaging in the form of diffusion-weighted imaging (DWI) is now part of the routine MR evaluation of the kidneys and has been found to be very useful in assessing the likely malignant potential of renal parenchymal masses and transitional cell neoplasms. The apparent diffusion coefficient (ADC) values of these neoplasms is significantly higher than those of normal renal parenchyma and normal urothelial mucosa. The ability of DWI to identify changes in the molecular level has dramatically changed the diagnostic approach of radiologists, which was solely heretofore based on morphological criteria. It can improve the diagnostic accuracy of conventional MRI, assist the assessment of tumor response to treatment regimens and detect tumor recurrence with better spatial resolution, negative radiation, and diagnostic accuracy compared to PET-CT. The ability to quantify the diffusion has also led to potential prediction of tumor aggressiveness and grade which directly correlate with patient prognosis and management.
